Received 27 December 2002; received in revised form 27 January 2005

Abstract

In this paper the pricing of European-style discrete arithmetic Asian options with fixed and floating strike is studied by deriving analytical lower and upper bounds. In our approach we use a general technique for deriving upper (and lower) bounds for stop-loss premiums of sums of dependent random variables, as explained in Kaas et al. (Ins. Math. Econom. 27 (2000) 151–168), and additionally, the ideas of Rogers and Shi (J. Appl. Probab. 32 (1995) 1077–1088) and of Nielsen and Sandmann (J. Financial Quant. Anal. 38(2) (2003) 449–473). We are able to create a unifying framework for European-style discrete arithmetic Asian options through these bounds, that generalizes several approaches in the literature as well as improves the existing results. We obtain analytical and easily computable bounds. The aim of the paper is to formulate an advice of the appropriate choice of the bounds given the parameters, investigate the effect of different conditioning variables and compare their efficiency numerically. Several sets of numerical results are included. We also discuss hedging using these bounds. Moreover, our methods are applicable to a wide range of (pricing) problems involving a sum of dependent random variables. © 2005 Elsevier B.V. All rights reserved.

1. Introduction

In this paper the pricing of European-style discrete arithmetic Asian options with fixed and floating strike is studied.

A European-style discrete arithmetic Asian call option is a financial derivative instrument with exercise date T , n averaging dates and fixed strike price K , which generates at T a pay-off

$$\left(\frac{1}{n} \sum_{i=0}^{n-1} S(T-i) - K \right)_+,$$

where $x_+ = \max\{x, 0\}$ and $S(T-i)$ is the price of a risky asset at time $T-i$, $i = 0, \dots, n-1$. The risk neutral price of this call option at current time $t = 0$ is given by

$$AC(n, K, T) = \frac{e^{-rT}}{n} E^Q \left[\left(\sum_{i=0}^{n-1} S(T-i) - nK \right)_+ \right] \quad (1)$$

under a martingale measure Q and with some risk-neutral interest rate r .

A European-style discrete arithmetic Asian put option with exercise date T , n averaging dates ($n \leq T+1$) and floating strike price with percentage β , generates at T a pay-off

$$\left(\frac{1}{n} \sum_{i=0}^{n-1} S(T-i) - \beta S(T) \right)_+.$$

A European-style arithmetic Asian call option with continuous averaging is based on a similar pay-off as in (1) but by replacing the discrete average by an integral divided by the length of the averaging period. We focus on discrete averaging which is the normal specification in real contracts. Discrete arithmetic Asian options are path-dependent contingent claims with pay-offs that depend on the average of the underlying asset price over some prespecified period of time, often a low number of trading days in the discrete averaging case. Such contracts form an attractive specification for thinly traded asset markets where price manipulation on or near a maturity date is possible. In markets where prices are prone to periods of extreme volatility the averaging performs a smoothing operation. For buyers as well as for writers, an Asian option is a useful hedging instrument. These Asian options provide for the buyer a cost efficient way of hedging cash or asset flows over extended periods, e.g., for foreign exchange, interest rate, or commodities like oil or gold. For the writer of an Asian option, the advantages include more manageable hedge ratios and the ability to unwind his position more gracefully at the end.

Asian options can also be part of complex financial contracts and strategies, like retirement plans or catastrophe insurance derivatives. Indeed, as explained in [19], a typical investment plan of a retirement scheme could include fixed periodic payments invested in a specified risky asset. An Asian option on the average return can be used to guarantee a minimum rate of return on the periodic payments. On the other hand, Cat-calls are catastrophic risk options which include Asian options on the average of an underlying index (see [12]).

Within the Black and Scholes [4] model, no closed form solutions are available for Asian options involving the discrete arithmetic average. As opposed to options on geometric average, the density function for the arithmetic average is not lognormal and has no explicit representation. A variety of methods for

the European case and especially continuously averaged fixed strike options have been developed while only a few papers deal with the more practical case of discrete arithmetic averaging. A partial list of methods includes (for references see for example, [17,25]): Monte Carlo or quasi-Monte Carlo methods, exact expressions involving Laplace transforms or an infinite sum over recursively defined integrals, convolution methods using the fast Fourier transform, analytic approximations based on moment matching or conditioning on some average, a number of PDE methods, tree methods.

We focus on analytic methods, based on bounds through conditioning on some random variable. We aim to create a unifying framework for European-style discrete arithmetic Asian options through these bounds, that generalizes several approaches in the literature as well as improves the existing results.

Throughout the paper we mainly consider ‘forward starting’ Asian options which means that at the current time 0, the averaging has not yet started and that the n variables $S(T - n + 1), \dots, S(T)$ are random. This case states in contrast with the case that $T - n + 1 \leq 0$ where only the prices $S(1), \dots, S(T)$ remain random. In the literature, this Asian option is called ‘in progress’. Note that our results for forward starting Asian options can immediately be translated to results for Asian options in progress. Most papers considering analytical approximations treat only standard Asian options which is the case of $T = n - 1$ but in a nonanalytical way the PDE approach also treats easily different types of Asian options.

An analytical lower and upper bound in the case of continuous averaging was obtained by the method of conditioning in [21]. Simon et al. [23] derived and computed in a general framework an analytical expression for the so-called ‘comonotonic upper bound’, which is in fact the smallest linear combination of prices of European call options that bounds the price of an European-style Asian option from above, and which corresponds with a static super-hedging strategy. Nielsen and Sandmann [19] studied both upper and lower bounds for an European-style arithmetic Asian option in the Black and Scholes setting. In particular, they derive a special case of the Simon et al. upper bound using Lagrange optimization. Nielsen and Sandmann [19] also apply the Rogers and Shi reasoning in the arithmetic averaging case by using one specific standardized normally distributed conditioning variable.

The paper is organized as follows. Section 2 provides bounds for the European-style discrete arithmetic Asian options with fixed strike in the Black and Scholes setting. We first present in Section 2.1 lower and upper bounds based on a general technique for deriving the bounds for stop-loss premiums of sums of dependent random variables, as explained in [15,9]. For clarity we have included a short overview of their methods in Appendix A. In Section 2.2 we show how to improve the upper bound that is based on the ideas of Rogers and Shi [21], and generalize the approach of Nielsen and Sandmann [19] to a general class of normally distributed conditioning variables. We also show in Section 2.3 how to sharpen the improved comonotonic upper bound of Kaas et al. [15] and Dhaene et al. [9] by obtaining another so-called partially exact/comonotonic upper bound which consists of an exact part of the option price and some improved comonotonic upper bound for the remaining part. This idea of decomposing the calculations in an exact part and an approximating part goes at least back to Curran [17]. The procedures we present can also be used to price the European-style discrete arithmetic Asian put options with fixed strike (either directly or through the put-call parity), see Section 2.4. In Section 2.5 we compare and discuss all approaches and, in addition, compare our results to those of Jacques [14], who approximates the distribution of the arithmetic average by a more tractable one. We measure the closeness of the bounds in distributional sense. Several sets of numerical results are given. We also consider hedging based on the lower and upper bounds in Section 2.6.

Section 3 treats the European-style discrete arithmetic Asian options with floating strike in the Black and Scholes setting. In independent work, Henderson and Wojakowski [13] use the change of numeraire

technique to obtain symmetry results between forward starting European-style Asian options with floating and fixed strike in case of continuous averaging. We show that their results can be extended to discrete averaging and we give also bounds for the European-style Asian floating strike options in progress.

We conclude the paper with main results and recent developments in Section 4.

One of the aims of this paper is to identify the currently best lower and upper bounds. We will show that the lower bounds are very close to the Monte Carlo values and that one of our techniques leads to very satisfying upper bounds, see Theorem 6.

2. Fixed strike Asian options in a Black and Scholes setting

In the Black and Scholes model, the price of a risky asset $\{S(t), t \geq 0\}$ under the risk-neutral measure Q follows a geometric Brownian motion process, with volatility σ and with drift equal to the risk-free force of interest r :

$$\frac{dS(t)}{S(t)} = r dt + \sigma dB(t), \quad t \geq 0,$$

where $\{B(t), t \geq 0\}$ is a standard Brownian motion process under Q . Hence, the random variables $S(t)/S(0)$ are lognormally distributed with parameters $(r - \frac{\sigma^2}{2})t$ and $t\sigma^2$.

As a consequence, we do not have an explicit analytical expression for the distribution of the average $\frac{1}{n} \sum_{i=0}^{n-1} S(T-i)$ in (1) and determining the price of the Asian option is a complicated task. From (1) it is seen that the problem of pricing arithmetic Asian options turns out to be equivalent to calculating stop-loss premiums of a sum of dependent risks. Hence we can apply the results on comonotonic upper and lower bounds for stop-loss premiums, which have been summarized in Section 2.1 and in Appendix A.

We shall now concentrate on bounds for the European-style discrete arithmetic Asian option with fixed strike by comonotonicity reasoning and by using the approach of Rogers and Shi which has been generalized in [19]. We only write down the formulae of the forward starting Asian call options as the Asian options in progress and the corresponding Asian put options can be treated in a similar way.

2.1. Bounds based on comonotonicity reasoning

In both financial and actuarial context one encounters quite often random variables of the type $\mathbb{S} = \sum_{i=1}^n X_i$ where the terms X_i are not mutually independent, but the multivariate distribution function of the random vector (X_1, X_2, \dots, X_n) is not completely specified because one only knows the marginal distribution functions of the random variables X_i . In such cases, one would like to find lower bounds of the form $\underline{\mathbb{S}} = \sum_{i=1}^n \underline{X}_i$ and upper bounds of the form $\overline{\mathbb{S}} = \sum_{i=1}^n \overline{X}_i$ for the sum $\mathbb{S} = \sum_{i=1}^n X_i$ such that (i) the marginal distribution functions of X_i , \underline{X}_i and \overline{X}_i ($i = 1, \dots, n$) are equal, and (ii) $\underline{\mathbb{S}} \leq_{\text{cx}} \mathbb{S} \leq_{\text{cx}} \overline{\mathbb{S}}$, where \leq_{cx} denotes the convex order, which means that $E[\underline{\mathbb{S}}] = E[\mathbb{S}] = E[\overline{\mathbb{S}}]$ and $E[(\underline{\mathbb{S}} - d)_+] \leq E[(\mathbb{S} - d)_+] \leq E[(\overline{\mathbb{S}} - d)_+]$ for all $d \in \mathbb{R}$.

Referring to Dhaene et al. [9], one possible choice for an upper bound $\overline{\mathbb{S}}$ is given by $\overline{\mathbb{S}} := \mathbb{S}^c$ with

$$\mathbb{S}^c \stackrel{d}{=} \sum_{i=1}^n F_{X_i}^{-1}(U). \quad (2)$$

In other words, we choose the components of the random vector $(\overline{X}_1, \overline{X}_2, \dots, \overline{X}_n)$ such that $\overline{X}_i := X_i^c := F_{X_i}^{-1}(U)$, where (a) $F_X^{-1}(U)$ is the usual inverse of a distribution function, evaluated at a uniform $(0,1)$ random variable U , which is the non-decreasing and left-continuous function defined by

$$F_X^{-1}(p) = \inf\{x \in \mathbb{R} \mid F_X(x) \geq p\}, \quad p \in [0, 1],$$

with $\inf \emptyset = +\infty$ by convention, and (b) the corresponding random vector (X_1^c, \dots, X_n^c) is *comonotonic*, which means that each two possible outcomes (x_1, \dots, x_n) and (y_1, \dots, y_n) of (X_1^c, \dots, X_n^c) are ordered componentwise.

Another choice for the upper bound $\overline{\mathbb{S}}$ is based on the assumption that there is some additional information available concerning the stochastic nature of (X_1, \dots, X_n) , represented by some random variable A with a given distribution function. Based on Kaas et al. [15], we choose $\overline{\mathbb{S}} := \mathbb{S}^u$, with

$$\mathbb{S}^u = F_{X_1|A}^{-1}(U) + F_{X_2|A}^{-1}(U) + \dots + F_{X_n|A}^{-1}(U). \quad (3)$$

To be more precise, we choose the components of the random vector $(\overline{X}_1, \overline{X}_2, \dots, \overline{X}_n)$ such that $\overline{X}_i := F_{X_i|A}^{-1}(U)$, where $F_{X_i|A}^{-1}(U)$ is the notation for the random variable $f_i(U, A)$, with the function f_i defined by $f_i(u, \lambda) = F_{X_i|A=\lambda}^{-1}(u)$, and with U being a $(0, 1)$ -uniform random variable independent of A . The upper bound \mathbb{S}^u is an improvement over the upper bound \mathbb{S}^c , see e.g. Dhaene et al. [9] for details.

As a lower bound we choose $\underline{\mathbb{S}} := \mathbb{S}^\ell$, following Kaas et al. [15], where \mathbb{S}^ℓ is a conditional expectation of \mathbb{S} given some random variable A , not necessarily equal to that entering (3):

$$\mathbb{S}^\ell = E[\mathbb{S} \mid A]. \quad (4)$$

In other words, we choose the components of the random vector $(\underline{X}_1, \underline{X}_2, \dots, \underline{X}_n)$ such that $\underline{X}_i := E[X_i \mid A]$. We remark that this idea was also suggested in [21] for the continuous averaging case.

Summarizing, the sum \mathbb{S} is bounded below and above in convex order by the sums given by (4), (3) and (2):

$$\mathbb{S}^\ell \preceq_{\text{cx}} \mathbb{S} \preceq_{\text{cx}} \mathbb{S}^u \preceq_{\text{cx}} \mathbb{S}^c,$$

which implies by definition of convex order that

$$E[(\mathbb{S}^\ell - d)_+] \leq E[(\mathbb{S} - d)_+] \leq E[(\mathbb{S}^u - d)_+] \leq E[(\mathbb{S}^c - d)_+]$$

for all $d \in \mathbb{R}$, while $E[\mathbb{S}^\ell] = E[\mathbb{S}] = E[\mathbb{S}^u] = E[\mathbb{S}^c]$.

A more detailed overview of the construction of these sums and the corresponding bounds, based on the literature, is given in Appendix A. Notice that throughout the paper, especially in the proofs of theorems, we make use of the results summarized in the appendix.

We remark that the Asian option pricing in the Black and Scholes setting is in fact a particular case of sums of lognormal variables in Appendix A. Indeed, let us look at the price of the European-style discrete arithmetic Asian call option with strike price K , maturity date T and averaging over n prices of the underlying with $T - n + 1 \geq 0$:

$$\text{AC}(n, K, T) = \frac{e^{-rT}}{n} E^Q[(\mathbb{S} - nK)_+] \quad (5)$$

with

$$\mathbb{S} = \sum_{i=0}^{n-1} S(T-i) = \sum_{i=0}^{n-1} S(0)e^{(r-\frac{\sigma^2}{2})(T-i)+\sigma B(T-i)}. \quad (6)$$

This can be rewritten as a sum of lognormal random variables:

$$\mathbb{S} = \sum_{i=0}^{n-1} X_i = \sum_{i=0}^{n-1} \alpha_i e^{Y_i} \quad (7)$$

with

$$Y_i = \sigma B(T-i) \sim N(0, \sigma^2(T-i)) \text{ and } \alpha_i = S(0)e^{(r-\frac{\sigma^2}{2})(T-i)} \quad (8)$$

and

$$\text{cov}(Y_i, Y_j) = \sigma^2 \min(T-i, T-j)$$

leading to

$$\text{cov}(X_i, X_j) = \alpha_i \alpha_j e^{((T-i)+(T-j))\sigma^2/2} [e^{\sigma^2 \min(T-i, T-j)} - 1].$$

2.1.1. Lower bound

A lower bound for the Asian option price $\text{AC}(n, K, T)$ is obtained by using a normally distributed conditioning variable Λ and by substituting \mathbb{S}^ℓ for \mathbb{S} in the right-hand side of (5), where according to (4)

$$\mathbb{S}^\ell = \sum_{i=0}^{n-1} E^Q[X_i | \Lambda] = \sum_{i=0}^{n-1} \alpha_i E^Q[e^{Y_i} | \Lambda].$$

The following theorem states a lower bound for the option price $\text{AC}(n, K, T)$. The proof follows from (62), (63) and (68) in Appendix A as shown in [10].

Theorem 1. Suppose the sum \mathbb{S} is given by (6)–(8) and Λ is a normally distributed conditioning variable such that $(\sigma B(T-i), \Lambda)$ are bivariate normally distributed for all i . Then the comonotonic lower bound for the option price $\text{AC}(n, K, T)$ is given by

$$\begin{aligned} \text{LBA} &= \frac{e^{-rT}}{n} E^Q[(\mathbb{S}^\ell - nK)_+] \\ &= \frac{S(0)}{n} \sum_{i=0}^{n-1} e^{-ri} \Phi[\sigma \rho_{T-i} \sqrt{T-i} - \Phi^{-1}(F_{\mathbb{S}^\ell}(nK))] - e^{-rT} K (1 - F_{\mathbb{S}^\ell}(nK)), \end{aligned} \quad (9)$$

where $\rho_{T-i} = \text{corr}(\sigma B(T-i), \Lambda) \geq 0$ and $F_{\mathbb{S}^\ell}(nK)$ is a solution to

$$S(0) \sum_{i=0}^{n-1} \exp \left[\left(r - \frac{\sigma^2}{2} \rho_{T-i}^2 \right) (T-i) + \sigma \rho_{T-i} \sqrt{T-i} \Phi^{-1}(F_{\mathbb{S}^\ell}(nK)) \right] = nK, \quad (10)$$

where $\Phi(\cdot)$ is the cumulative distribution function (cdf) of a standard normal variable and $F_{\mathbb{S}^\ell}(\cdot)$ represents the cdf of \mathbb{S}^ℓ .

Note that the conditioning variable A only enters through the correlations ρ_{T-i} . We now focus on choosing the appropriate conditioning variable A . Taking into account that we aim to derive a closed-form expression for the lower bound, we define A as a normal random variable given by

$$A = \sum_{i=0}^{n-1} \beta_i B(T-i), \quad \beta_i \in \mathbb{R}^+. \quad (11)$$

For general positive β_i , the variance of A is given by

$$\sigma_A^2 = \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} \beta_i \beta_j \min(T-i, T-j)$$

and

$$\rho_{T-i} = \text{corr}(\sigma B(T-i), A) = \frac{\text{cov}(B(T-i), A)}{\sqrt{T-i} \sigma_A} = \frac{\sum_{j=0}^{n-1} \beta_j \min(T-i, T-j)}{\sqrt{T-i} \sigma_A} \geq 0. \quad (12)$$

Remark that we take positive coefficients β_i implying that the correlations ρ_{T-i} are positive. This is to ensure that \mathbb{S}^ℓ is a sum of n comonotonic random variables.

We investigate different choices of weights β_i in expression (11) for the conditioning random variable A . The choice is motivated by the reasoning that the quality of the stochastic lower bound $E^Q[\mathbb{S} | A]$ can be judged by its variance. To maximize the quality, this variance should be made as close as possible to $\text{var}^Q[\mathbb{S}]$. In other words, the average value

$$E^Q[\text{var}^Q[\mathbb{S} | A]] = \text{var}^Q[\mathbb{S}] - \text{var}^Q[E^Q[\mathbb{S} | A]]$$

should be small. This however does not imply that the above expression should be minimized over the conditioning variable A . Notice that

$$\text{var}^Q[\mathbb{S}] - \text{var}^Q[\mathbb{S}^\ell] = 2 \int_{-\infty}^{+\infty} \{E^Q[(\mathbb{S} - k)_+] - E^Q[(\mathbb{S}^\ell - k)_+]\} dk.$$

From this relation it is seen that minimizing the difference in variance over A is no guarantee that the difference between the corresponding stop-loss premia for one particular k will be minimized. Intuitively, to get the best lower bound for $\text{AC}(n, K, T)$, A and \mathbb{S} should be as alike as possible. Therefore, we have selected the following two candidates for A which turn out to give very good results:

1. a linear transformation of a first-order approximation to $\sum_{i=0}^{n-1} S(T-i)$ in (6), as proposed in a general setting in [15] and used in [10]:

$$A = \sum_{i=0}^{n-1} e^{(r - \frac{\sigma^2}{2})(T-i)} B(T-i), \quad (13)$$

2. the standardized logarithm of the geometric average $\mathbb{G} = \sqrt[n]{\prod_{i=0}^{n-1} S(T-i)}$ as in [19]:

$$A = \frac{\ln \mathbb{G} - E^Q[\ln \mathbb{G}]}{\sqrt{\text{var}^Q[\ln \mathbb{G}]}} = \frac{1}{\sqrt{\text{var}^Q[\sum_{i=0}^{n-1} B(T-i)]}} \sum_{i=0}^{n-1} B(T-i), \quad (14)$$

where

$$\text{var}^Q \left[\sum_{i=0}^{n-1} B(T-i) \right] = \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} \min(T-i, T-j) = n^2 T - \frac{n}{6} (n-1)(4n+1).$$

The lower bound (9)–(10) differs for the two choices (13) and (14) of A , only by expression (12) for the correlation coefficient ρ_{T-i} :

$$\begin{aligned} 1. \quad \rho_{T-i} &= \frac{\sum_{j=0}^{n-1} e^{(r-\frac{\sigma_A^2}{2})(T-j)} \min(T-i, T-j)}{\sqrt{T-i} \sigma_A} \\ &\text{with } \sigma_A^2 = \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} e^{(r-\frac{\sigma_A^2}{2})(2T-i-j)} \min(T-i, T-j), \\ 2. \quad \rho_{T-i} &= \frac{\sum_{j=0}^{n-1} \min(T-i, T-j)}{\sqrt{n^2 T - \frac{n}{6}(n-1)(4n+1)} \sqrt{T-i}} = \frac{n(T-i) - (n-i-1)(n-i)/2}{\sqrt{n^2 T - \frac{n}{6}(n-1)(4n+1)} \sqrt{T-i}} \\ &\text{since } \sigma_A = 1. \end{aligned}$$

We note that the closed-form solution of the lower bound in Nielsen and Sandmann [19] is a special case of (9) and (10) with (14) as the conditioning variable. We also notice that the lower bound when conditioning on the geometric average coincides with the so-called “naive” approximation of Curran [7]. In fact, formulae (9)–(10) for the lower bound are general in the sense that they hold for any normally distributed conditioning variable A , satisfying the assumptions of Theorem 1, by substituting the right ρ_{T-i} . Moreover, the lower bound can be expressed as a combination of Black and Scholes type formulae.

Theorem 2. For a general normally distributed conditioning variable A , satisfying the assumptions of Theorem 1, the lower bound LBA of $\text{AC}(n, K, T)$ can be written as an average of Black and Scholes formulae for an artificial underlying asset of which the price process $\tilde{S}(t)$ is a geometric Brownian motion with $\tilde{S}(0) = S(0)$ and with a nonconstant volatility $\tilde{\sigma}_i = \sigma \rho_{T-i}$ at time instance $T-i$:

$$\text{LBA} = \frac{e^{-rT}}{n} \sum_{i=0}^{n-1} E^Q[(\tilde{S}(T-i) - \tilde{K}_i)_+] = \frac{1}{n} \sum_{i=0}^{n-1} (e^{-ri} \tilde{S}(0) \Phi(d_{1,i}) - e^{-rT} \tilde{K}_i \Phi(d_{2,i}))$$

with

$$\tilde{S}(T-i) = \tilde{S}(0) e^{(r-\frac{\tilde{\sigma}_i^2}{2})(T-i) + \tilde{\sigma}_i B(T-i)}$$

and strike prices

$$\tilde{K}_i = F_{E[S(T-i)|A]}^{-1}(F_{\mathbb{S}^\ell(nK)}) = S(0) e^{(r-\frac{\tilde{\sigma}_i^2}{2})(T-i) + \tilde{\sigma}_i \sqrt{T-i} \Phi^{-1}(F_{\mathbb{S}^\ell(nK)})}$$

and where

$$d_{1,i} = \frac{(r + (\tilde{\sigma}_i^2/2))(T-i) - \ln(\tilde{K}_i/\tilde{S}(0))}{\tilde{\sigma}_i \sqrt{T-i}} = \tilde{\sigma}_i \sqrt{T-i} - \Phi^{-1}(F_{\mathbb{S}^\ell(nK)}),$$

$$d_{2,i} = d_{1,i} - \tilde{\sigma}_i \sqrt{T-i} = -\Phi^{-1}(F_{\mathbb{S}^\ell(nK)})$$

while $F_{\mathbb{S}^\ell(nK)}$ can be calculated from $\sum_{i=0}^{n-1} \tilde{K}_i = nK$ similarly to (10).

2.1.2. Improved comonotonic upper bound

As for the lower bound, we consider a conditioning normal random variable Λ . An improved comonotonic upper bound for the Asian option price $AC(n, K, T)$ is given by

$$AC(n, K, T) = \frac{e^{-rT}}{n} E^Q[(\mathbb{S} - nK)_+] \leq \frac{e^{-rT}}{n} E^Q[(\mathbb{S}^u - nK)_+], \quad (15)$$

where according to (3) $\mathbb{S}^u = \sum_{i=0}^{n-1} F_{X_i|\Lambda}^{-1}(U) = \sum_{i=0}^{n-1} F_{\alpha_i e^{Y_i}|\Lambda}^{-1}(U)$ for a $(0, 1)$ -uniform random variable U independent of Λ . More explicitly, we obtain the following analytic expression for this bound:

Theorem 3. Suppose the sum \mathbb{S} is given by (6)–(8) and Λ is a normally distributed conditioning variable such that $(\sigma B(T-i), \Lambda)$ are bivariate normally distributed for all i . Then the improved comonotonic upper bound for the option price $AC(n, K, T)$ is given by

$$\begin{aligned} ICUB\Lambda &= \frac{e^{-rT}}{n} E^Q[(\mathbb{S}^u - nK)_+] \\ &= \frac{e^{-rT}}{n} \sum_{i=0}^{n-1} S(0) e^{r(T-i)} e^{-\frac{\sigma^2}{2} \rho_{T-i}^2 (T-i)} \\ &\quad \times \int_0^1 e^{\rho_{T-i} \sigma \sqrt{T-i} \Phi^{-1}(v)} \Phi(\sqrt{1 - \rho_{T-i}^2} \sigma \sqrt{T-i} - \Phi^{-1}(F_{\mathbb{S}^u|V=v}(nK))) dv \\ &\quad - e^{-rT} nK (1 - F_{\mathbb{S}^u}(nK)), \end{aligned} \quad (16)$$

where

$$V = \Phi\left(\frac{\Lambda - E[\Lambda]}{\sigma_\Lambda}\right) \quad (17)$$

is a uniform $(0, 1)$ random variable, $\rho_{T-i} = \text{corr}(\sigma B(T-i), \Lambda)$, and

$$F_{\mathbb{S}^u}(nK) = \int_0^1 F_{\mathbb{S}^u|V=v}(nK) dv$$

and the conditional distribution $F_{\mathbb{S}^u|V=v}(nK)$ follows from

$$nK = \sum_{i=0}^{n-1} \alpha_i \exp[\rho_{T-i} \sigma \sqrt{T-i} \Phi^{-1}(v) + \sqrt{1 - \rho_{T-i}^2} \sigma \sqrt{T-i} \Phi^{-1}(F_{\mathbb{S}^u|V=v}(nK))]. \quad (18)$$

Proof. We determine the cdf of \mathbb{S}^u and the stop-loss premium $E[(\mathbb{S}^u - d)_+]$, where we condition on a normally distributed random variable Λ or equivalently on the uniform $(0, 1)$ random variable V , cf. (17). The conditional probability $F_{\mathbb{S}^u|V=v}(x)$ also denoted by $F_{\mathbb{S}^u}(x | V=v)$, is the cdf of a sum of n comonotonic random variables and follows for $F_{\mathbb{S}^u|V=v}^{-1}(0) < x < F_{\mathbb{S}^u|V=v}^{-1}(1)$, according to (60) and (67), for $\alpha_i \geq 0, i = 0, \dots, n-1$, implicitly from:

$$\sum_{i=0}^{n-1} \alpha_i e^{E[Y_i] + r_i \sigma_{Y_i} \Phi^{-1}(v) + \sqrt{1 - r_i^2} \sigma_{Y_i} \Phi^{-1}(F_{\mathbb{S}^u}(x|V=v))} = x, \quad (19)$$

where $r_i = \text{corr}(Y_i, A)$. The cdf of \mathbb{S}^u is then given by

$$F_{\mathbb{S}^u}(x) = \int_0^1 F_{\mathbb{S}^u|V=v}(x) dv. \quad (20)$$

We now look for an expression for the stop-loss premium at retention d with $F_{\mathbb{S}^u|V=v}^{-1}(0) < d < F_{\mathbb{S}^u|V=v}^{-1}(1)$ for \mathbb{S}^u , see (61):

$$E[(\mathbb{S}^u - d)_+] = \int_0^1 E[(\mathbb{S}^u - d)_+ | V = v] dv = \sum_{i=0}^{n-1} \int_0^1 E[(F_{X_i|A}^{-1}(U | V = v) - d)_+] dv \quad (21)$$

with $d_i = F_{X_i|A}^{-1}(F_{\mathbb{S}^u}(d | V = v) | V = v)$ and with U a random variable which is uniformly distributed on $(0, 1)$ and independent of V . Since $F_{X_i|A}^{-1}(U | V = v)$ follows a lognormal distribution with mean and standard deviation:

$$\mu_v(i) = \ln \alpha_i + E[Y_i] + r_i \sigma_{Y_i} \Phi^{-1}(v), \quad \sigma_v(i) = \sqrt{1 - r_i^2} \sigma_{Y_i},$$

one obtains that

$$d_i = \alpha_i \exp[E[Y_i] + r_i \sigma_{Y_i} \Phi^{-1}(v) + \alpha_i \sqrt{1 - r_i^2} \sigma_{Y_i} \Phi^{-1}(F_{\mathbb{S}^u|V=v}(d))]. \quad (22)$$

The well-known formula (65) then yields

$$E[(\mathbb{S}^u - d)_+ | V = v] = \sum_{i=0}^{n-1} [\alpha_i e^{\mu_v(i) + \frac{\sigma_v^2(i)}{2}} \Phi(\alpha_i d_{i,1}) - d_i \Phi(\alpha_i d_{i,2})],$$

with, according to (66),

$$d_{i,1} = \frac{\mu_v(i) + \sigma_v^2(i) - \ln d_i}{\sigma_v(i)}, \quad d_{i,2} = d_{i,1} - \sigma_v(i).$$

Substitution of the corresponding expressions and integration over the interval $[0, 1]$ leads to the following result:

$$\begin{aligned} E[(\mathbb{S}^u - d)_+] &= \sum_{i=0}^{n-1} \alpha_i e^{E[Y_i] + \frac{1}{2} \sigma_{Y_i}^2 (1 - r_i^2)} \\ &\quad \times \int_0^1 e^{r_i \sigma_{Y_i} \Phi^{-1}(v)} \Phi(\text{sign}(\alpha_i) \sqrt{1 - r_i^2} \sigma_{Y_i} - \Phi^{-1}(F_{\mathbb{S}^u|V=v}(d))) dv \\ &\quad - d(1 - F_{\mathbb{S}^u}(d)). \end{aligned} \quad (23)$$

The upper bound then follows from (19) and (23) for $d = nK$ by plugging in α_i , Y_i and its mean and variance from (8), while denoting the correlations r_i by ρ_{T-i} . \square

We found that the conditioning variable

$$A = \sum_{k=1}^T \beta_k W_k, \quad \text{with } W_k \text{ i.i.d. } N(0, 1) \text{ such that } B(T-i) \stackrel{d}{=} \sum_{k=1}^{T-i} W_k, \quad i = 0, \dots, n-1, \quad (24)$$

with all β_k equal to a same constant (for simplicity taken equal to one) leads to a sharper upper bound than other choices for β_k or than the conditioning variables in the lower bound.

For $\Lambda = \sum_{k=1}^T W_k \stackrel{d}{=} B(T)$ the correlation terms have the form:

$$r_i = \rho_{T-i} = \frac{\text{cov}(B(T-i), \Lambda)}{\sqrt{T-i}\sigma_\Lambda} = \frac{T-i}{\sqrt{T-i}\sqrt{T}} = \frac{\sqrt{T-i}}{\sqrt{T}}, \quad i = 0, \dots, n-1 \quad (25)$$

and the dependence structure of the terms in the sum \mathbb{S}^u corresponds better to that of the terms in the sum \mathbb{S} than for other choices of Λ . Investigating the correlations

$$\begin{aligned} \text{corr}[F_{S(T-i)|\Lambda}^{-1}(U), F_{S(T-j)|\Lambda}^{-1}(U)] &= \frac{e^{[\rho_{T-i}\rho_{T-j} + \sqrt{1-\rho_{T-i}^2}\sqrt{1-\rho_{T-j}^2}]\sigma^2\sqrt{T-i}\sqrt{T-j}} - 1}{\sqrt{e^{\sigma^2(T-i)} - 1}\sqrt{e^{\sigma^2(T-j)} - 1}}, \\ \text{corr}[S(T-i), S(T-j)] &= \frac{e^{\sigma^2 \min(T-i, T-j)} - 1}{\sqrt{e^{\sigma^2(T-i)} - 1}\sqrt{e^{\sigma^2(T-j)} - 1}}, \end{aligned}$$

it can be seen that for ρ_{T-i} given by (25) these correlations not only coincide for $i = j$ but also when one of the indices i or j equals zero. Moreover, for $i \neq j$, the differences

$$|[\rho_{T-i}\rho_{T-j} + \sqrt{1-\rho_{T-i}^2}\sqrt{1-\rho_{T-j}^2}]\sigma^2\sqrt{T-i}\sqrt{T-j} - \sigma^2 \min(T-i, T-j)|$$

are small for all i and j in $\{0, \dots, n-1\}$ in comparison to other choices of Λ .

As in the case of the lower bound, we can rewrite the upper bound as an expression of Black and Scholes formulae.

Theorem 4. For a general normally distributed conditioning variable Λ , satisfying the assumptions of Theorem 1, the improved upper bound of $\text{AC}(n, K, T)$ can be written as a combination of Black and Scholes formulae for an artificial underlying asset $\tilde{S}(t)$ with $\tilde{S}(0) = S(0)$ and with volatilities $\tilde{\sigma}_i = \sigma\sqrt{1-\rho_{T-i}^2}$:

$$\begin{aligned} \frac{e^{-rT}}{n} E^Q[(\mathbb{S}^u - nK)_+] &= \int_0^1 \frac{1}{n} \sum_{i=0}^{n-1} e^{\rho_{T-i}\sigma\sqrt{T-i}\Phi^{-1}(v) - \frac{\sigma^2}{2}\rho_{T-i}^2(T-i)} \\ &\quad \times \{e^{-ri}\tilde{S}(0)\Phi(d_{1,i}(v)) - e^{-rT}\tilde{K}_i(v)\Phi(d_{2,i}(v))\} dv \end{aligned}$$

with

$$\tilde{S}(T-i) = \tilde{S}(0)e^{(r-\frac{\tilde{\sigma}_i^2}{2})(T-i) + \tilde{\sigma}_i B(T-i)}$$

and the strike prices defined by

$$\tilde{K}_i(v) = S(0)e^{(r-\frac{\tilde{\sigma}_i^2}{2})(T-i) + \tilde{\sigma}_i\sqrt{T-i}\Phi^{-1}(F_{\mathbb{S}^u|V=v}(nK))},$$

where

$$d_{1,i}(v) = \frac{(r + (\tilde{\sigma}_i^2/2))(T-i) - \ln(\tilde{K}_i(v)/\tilde{S}(0))}{\tilde{\sigma}_i\sqrt{T-i}} = \tilde{\sigma}_i\sqrt{T-i} - \Phi^{-1}(F_{\mathbb{S}^u|V=v}(nK)),$$

$$d_{2,i}(v) = d_{1,i}(v) - \tilde{\sigma}_i \sqrt{T-i} = -\Phi^{-1}(F_{\mathbb{S}^u|V=v}(nK))$$

and $F_{\mathbb{S}^u|V=v}(nK)$ can be calculated similarly to (18) from $\sum_{i=0}^{n-1} \tilde{K}_i(v) = nK$.

2.2. Bounds based on the Rogers and Shi approach

As an alternative to Section 2.1.2, following the ideas of Rogers and Shi [21], we derive an upper bound based on the lower bound. Indeed, we apply the following general inequality for any random variable Y and Z from Rogers and Shi [21]:

$$0 \leq E[E[Y_+ | Z] - E[Y | Z]_+] \leq \frac{1}{2} E[\sqrt{\text{var}(Y | Z)}]. \quad (26)$$

Theorem 5. Let \mathbb{S} be given by (6)–(8) and Λ is a normally distributed conditioning variable such that $(\sigma B(T-i), \Lambda)$ are bivariate normally distributed for all i . Then an upper bound of the option price $\text{AC}(n, K, T)$ is given by

$$\text{UBA} = \frac{e^{-rT}}{n} \{E^Q[(\mathbb{S}^\ell - nK)_+] + \varepsilon\}, \quad (27)$$

where the error bound ε equals

$$\begin{aligned} \varepsilon = \frac{1}{2} E^Q[\sqrt{\text{var}^Q(\mathbb{S} | \Lambda)}] &= \frac{1}{2} \int_0^1 \left\{ \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} \alpha_i \alpha_j e^{r_{ij} \sigma \sigma_{ij} \Phi^{-1}(v) + \frac{1}{2} (1-r_{ij}^2) \sigma^2 \sigma_{ij}^2} \right. \\ &\quad \left. - \left(\sum_{i=0}^{n-1} S(0) e^{(r - \frac{1}{2} \sigma^2 \rho_{T-i}^2)(T-i) + \rho_{T-i} \sigma \sqrt{T-i} \Phi^{-1}(v)} \right)^2 \right\}^{1/2} dv, \end{aligned} \quad (28)$$

with

$$\alpha_i \alpha_j = S(0)^2 \exp \left[\left(r - \frac{\sigma^2}{2} \right) (2T - i - j) \right], \quad (29)$$

$$\sigma_{ij} = \sqrt{(T-i) + (T-j) + 2 \min(T-i, T-j)}, \quad (30)$$

$$r_{ij} = \frac{\sqrt{T-i}}{\sigma_{ij}} \rho_{T-i} + \frac{\sqrt{T-j}}{\sigma_{ij}} \rho_{T-j}. \quad (31)$$

Proof. By applying (26) to the case of Y being $\sum_{i=0}^{n-1} S(T-i) - nK$ and Z being a conditioning variable Λ , we obtain an error bound for the difference of the option price and its lower bound

$$0 \leq E^Q[E^Q[(\mathbb{S} - nK)_+ | \Lambda] - (\mathbb{S}^\ell - nK)_+] \leq \frac{1}{2} E^Q[\sqrt{\text{var}^Q(\mathbb{S} | \Lambda)}]. \quad (32)$$

Consequently, (27) follows after discounting as the upper bound for the option price $\text{AC}(n, K, T)$.

Using properties of lognormal distributed variables, $E^Q[\sqrt{\text{var}^Q(\mathbb{S} | A)}]$ can be written out explicitly, giving some lengthy, analytical, computable expression:

$$\begin{aligned} E^Q[\sqrt{\text{var}^Q(\mathbb{S} | A)}] &= E^Q[(E^Q[\mathbb{S}^2 | A] - E^Q[\mathbb{S} | A]^2)^{1/2}] \\ &= E^Q \left[\left(\sum_{i=0}^{n-1} \sum_{j=0}^{n-1} E^Q[S(T-i)S(T-j) | A] - (\mathbb{S}^\ell)^2 \right)^{1/2} \right], \end{aligned} \quad (33)$$

where the first term in the expectation in the right-hand side equals

$$\sum_{i=0}^{n-1} \sum_{j=0}^{n-1} \alpha_i \alpha_j \exp \left(r_{ij} \sigma \sigma_{ij} \Phi^{-1}(V) + \frac{1}{2} (1 - r_{ij}^2) \sigma^2 \sigma_{ij}^2 \right), \quad (34)$$

where V is uniformly distributed on the interval $(0, 1)$. The second term in the expectation in the right-hand side of (33) can according to (68) in Theorem 12 be written as

$$\mathbb{S}^\ell = \sum_{i=0}^{n-1} S(0) e^{(r - \frac{1}{2} \sigma^2 \rho_{T-i}^2)(T-i) + \rho_{T-i} \sigma \sqrt{T-i} \Phi^{-1}(V)} \quad (35)$$

by plugging in α_i , Y_i and its mean and variance from (8), while denoting the correlations r_i by ρ_{T-i} , and simplifying. \square

Note that the error bound (32) and hence ε are independent of the strike price K . In the following theorem we show how to strengthen the error bound ε in Theorem 5 by making it dependent on the strike price through a suitably chosen constant d_A such that $A \geq d_A$ implies that $\mathbb{S} \geq nK$. The meaning of finding such d_A for a general conditioning variable A is seen from the fact that we have on the set $\{A \geq d_A\}$ the relation:

$$E^Q[(\mathbb{S} - nK)_+ | A] = E^Q[\mathbb{S} - nK | A] = (\mathbb{S}^\ell - nK)_+. \quad (36)$$

The following theorem can be seen as a generalization of the corresponding result in [19]. Whereas Nielsen and Sandmann [19] derived their result directly for A given by (14), we extend this approach to any normally distributed conditioning random variable A .

Theorem 6. *Let \mathbb{S} be given by (6)–(8) and A is a normally distributed conditioning variable such that $(\sigma B(T-i), A)$ are bivariate normally distributed for all i . Suppose there exists a $d_A \in \mathbb{R}$ such that $A \geq d_A$ implies that $\mathbb{S} \geq nK$. Then an upper bound to the option price $\text{AC}(n, K, T)$ is given by*

$$\text{UB}A_d = \text{LBA} + \frac{e^{-rT}}{n} \varepsilon(d_A), \quad (37)$$

where the error bound $\varepsilon(d_A)$ is given by

$$\begin{aligned} \varepsilon(d_A) &= \frac{S(0)}{2} \{\Phi(d_A^*)\}^{1/2} \\ &\times \left\{ \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} e^{r(2T-i-j)+\sigma^2\rho_{T-i}\rho_{T-j}\sqrt{T-i}\sqrt{T-j}} \Phi(d_A^* - \sigma(\rho_{T-i}\sqrt{T-i} + \rho_{T-j}\sqrt{T-j})) \right. \\ &\times \left. (e^{\sigma^2(\min(T-i,T-j)-\rho_{T-i}\rho_{T-j}\sqrt{T-i}\sqrt{T-j})} - 1) \right\}^{1/2}, \end{aligned} \quad (38)$$

with $d_A^* = (d_A - E^Q[A])/\sigma_A$, $\Phi(\cdot)$ the standard normal cdf and $\rho_{T-i} = \text{corr}(\sigma B(T-i), A) \geq 0$.

Proof. In general, for $d_A \in \mathbb{R}$ such that $A \geq d_A$ implies that $\mathbb{S} \geq nK$, it follows by (36) that

$$\begin{aligned} 0 &\leq E^Q[E^Q[(\mathbb{S} - nK)_+ | A] - (\mathbb{S}^\ell - nK)_+] \\ &= \int_{-\infty}^{d_A} (E^Q[(\mathbb{S} - nK)_+ | A = \lambda] - (E^Q[\mathbb{S} | A = \lambda] - nK)_+) dF_A(\lambda) \\ &\leq \frac{1}{2} \int_{-\infty}^{d_A} (\text{var}^Q(\mathbb{S} | A = \lambda))^{1/2} dF_A(\lambda) \end{aligned} \quad (39)$$

$$\leq \frac{1}{2} (E^Q[\text{var}^Q(\mathbb{S} | A) 1_{\{A < d_A\}}])^{1/2} (E^Q[1_{\{A < d_A\}}])^{1/2} =: \varepsilon(d_A), \quad (40)$$

where Hölder's inequality has been applied in the last inequality, where $1_{\{A < d_A\}}$ is the indicator function, and where $F_A(\cdot)$ denotes the normal cumulative distribution function of A .

The first expectation term in the product (40) can be expressed as

$$E^Q[\text{var}^Q(\mathbb{S} | A) 1_{\{A < d_A\}}] = E^Q[E^Q[\mathbb{S}^2 | A] 1_{\{A < d_A\}}] - E^Q[(E^Q[\mathbb{S} | A])^2 1_{\{A < d_A\}}]. \quad (41)$$

The second term of the right-hand side of (41) can according to (35) be rewritten as

$$\begin{aligned} E^Q[(E^Q[\mathbb{S} | A])^2 1_{\{A < d_A\}}] &= \int_{-\infty}^{d_A} (E^Q[\mathbb{S} | A = \lambda])^2 dF_A(\lambda) \\ &= S(0)^2 \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} e^{r(2T-i-j)-\frac{\sigma^2}{2}(\rho_{T-i}^2(T-i)+\rho_{T-j}^2(T-j))} \\ &\times \int_{-\infty}^{d_A} e^{\sigma(\rho_{T-i}\sqrt{T-i}+\rho_{T-j}\sqrt{T-j})\Phi^{-1}(v)} dF_A(\lambda), \end{aligned} \quad (42)$$

where we recall that $\Phi^{-1}(v) = (\lambda - E^Q[\Lambda])/\sigma_\Lambda$ and $\Phi(\cdot)$ is the cumulative distribution function of a standard normal variable. Applying the equality

$$\int_{-\infty}^{d_\Lambda} e^{b\Phi^{-1}(v)} dF_\Lambda(\lambda) = e^{\frac{b^2}{2}} \Phi(d_\Lambda^* - b), \quad d_\Lambda^* = \frac{d_\Lambda - E^Q[\Lambda]}{\sigma_\Lambda}, \quad (43)$$

with $b = \sigma(\rho_{T-i}\sqrt{T-i} + \rho_{T-j}\sqrt{T-j})$ we can express $E^Q[(E^Q[\mathbb{S}|\Lambda])^2 1_{\{\Lambda < d_\Lambda\}}]$ as

$$S(0)^2 \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} e^{r(2T-i-j) + \sigma^2 \rho_{T-i} \rho_{T-j} \sqrt{T-i} \sqrt{T-j}} \Phi(d_\Lambda^* - \sigma(\rho_{T-i}\sqrt{T-i} + \rho_{T-j}\sqrt{T-j})). \quad (44)$$

To transform the first term of the right-hand side of (41) we invoke (29)–(31) and apply (43) with $b = r_{ij}\sigma\sigma_{ij} = \sigma(\rho_{T-i}\sqrt{T-i} + \rho_{T-j}\sqrt{T-j})$:

$$\begin{aligned} & E^Q[E^Q[\mathbb{S}^2|\Lambda] 1_{\{\Lambda < d_\Lambda\}}] \\ &= \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} \int_{-\infty}^{d_\Lambda} E^Q[S(T-i)S(T-j)|\Lambda = \lambda] dF_\Lambda(\lambda) \\ &= S(0)^2 \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} e^{(r - \frac{\sigma^2}{2})(2T-i-j) + \frac{1}{2}(1-r_{ij}^2)\sigma^2\sigma_{ij}^2} \int_{-\infty}^{d_\Lambda} e^{r_{ij}\sigma\sigma_{ij}\Phi^{-1}(v)} dF_\Lambda(\lambda) \\ &= S(0)^2 \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} e^{r(2T-i-j) + \sigma^2 \min(T-i, T-j)} \Phi(d_\Lambda^* - \sigma(\rho_{T-i}\sqrt{T-i} + \rho_{T-j}\sqrt{T-j})). \quad (45) \end{aligned}$$

The second expectation term in product (40) equals $F_\Lambda(d_\Lambda) = \Phi(d_\Lambda^*)$.

Combining (44) and (45) into (41), and then substituting $\Phi(d_\Lambda^*)$ and (41) into (40) finally leads to expression (38). \square

We stress that the error bound (40) and thus (38) hold for any conditioning normal random variable Λ that satisfies the assumptions of Theorem 1 and for which there exists an integration bound d_Λ such that $\Lambda \geq d_\Lambda$ implies $\mathbb{S} \geq nK$. For Λ given by (14), Nielsen and Sandmann found that the corresponding d_Λ is given by

$$d_{\text{GA}} = \frac{n \ln(K/S(0)) - \sum_{i=0}^{n-1} (r - \frac{\sigma^2}{2})(T-i)}{\sigma \sqrt{n^2 T - \frac{1}{6}n(n-1)(4n+1)}}, \quad (46)$$

where the subscript GA is to remind the fact that Λ is the standardized logarithm of the geometric average. The error bound (38) coincides with the one found in [19] for the special choice (14) for Λ and the corresponding d_{GA} (46). Let us show that also for Λ given by (13) this technique works to strengthen the error bound (32) and hence to sharpen the upper bound (27). Using the property that $e^x \geq 1 + x$ and

relations (6)–(8) and (13), we obtain

$$\mathbb{S} = \sum_{i=0}^{n-1} \alpha_i e^{Y_i} \geq \sum_{i=0}^{n-1} \alpha_i + S(0)\sigma \underbrace{\sum_{i=0}^{n-1} e^{(r-\frac{\sigma^2}{2})(T-i)} B(T-i)}_{=\Lambda}.$$

Hence $\mathbb{S} \geq nK$ when Λ is larger than $(nK - \sum_{i=0}^{n-1} \alpha_i)/(S(0)\sigma)$. Thus in case of Λ being a linear transformation of the first-order approximation (FA) of \mathbb{S} , we have

$$d_{\text{FA}} = \frac{nK - \sum_{i=0}^{n-1} S(0)e^{(r-\frac{\sigma^2}{2})(T-i)}}{S(0)\sigma}. \quad (47)$$

Let us also notice that the upper bound (27) corresponds to the limiting case of (39) where d_Λ equals infinity. Further note that in contrast to (32) the error bound now depends on K through d_Λ .

2.3. Partially exact/comonotonic upper bound

Next we combine the technique for obtaining an improved comonotonic upper bound by conditioning on some normally distributed random variable Λ and the idea of decomposing the calculations in an exact part and an approximating part which goes at least back to Curran [9]. This so-called partially exact/comonotonic upper bound consists of an exact part of the option price and some improved comonotonic upper bound for the remaining part. This upper bound improves the upper bound denoted by $C_A^{*,G}$ in the paper of Nielsen and Sandmann [19], as will be explained at the end of this section.

Theorem 7. Let \mathbb{S} be given by (6)–(8) and Λ be a normally distributed conditioning variable such that $(\sigma B(T-i), \Lambda)$ are bivariate normally distributed for all i . Suppose there exists a $d_\Lambda \in \mathbb{R}$ such that $\Lambda \geq d_\Lambda$ implies that $\mathbb{S} \geq nK$. Then the partially exact/comonotonic upper bound to the option price $\text{AC}(n, K, T)$ is given by

$$\begin{aligned} \text{PECUB}_\Lambda &= \frac{S(0)}{n} \sum_{i=0}^{n-1} e^{-ri} \Phi(\rho_{T-i} \sigma \sqrt{T-i} - d_\Lambda^*) - e^{-rT} K \Phi(-d_\Lambda^*) \\ &+ \frac{S(0)}{n} \sum_{i=0}^{n-1} e^{-ri} e^{-\frac{\sigma^2}{2} \rho_{T-i}^2 (T-i)} \\ &\times \int_0^{\Phi(d_\Lambda^*)} e^{\rho_{T-i} \sigma \sqrt{T-i} \Phi^{-1}(v)} \Phi(\sqrt{1 - \rho_{T-i}^2} \sigma \sqrt{T-i} - \Phi^{-1}(F_{\mathbb{S}^u|V=v}(nK))) \, dv \\ &- e^{-rT} K \left(\Phi(d_\Lambda^*) - \int_0^{\Phi(d_\Lambda^*)} F_{\mathbb{S}^u|V=v}(nK) \, dv \right), \end{aligned} \quad (48)$$

where $d_\Lambda^* = (d_\Lambda - E^Q[\Lambda])/\sigma_\Lambda$ and $F_{\mathbb{S}^u|V=v}$ is given by (18) and $\rho_{T-i} = \text{corr}(\sigma B(T-i), \Lambda)$.

Proof. For any normally distributed random variable A , with cdf $F_A(\cdot)$, for which there exists a d_A such that $A \geq d_A$ implies $\mathbb{S} \geq nK$ and which satisfies the assumptions of Theorem 1, we can write

$$\begin{aligned} \frac{e^{-rT}}{n} E^Q[(\mathbb{S} - nK)_+] &= \frac{e^{-rT}}{n} E^Q[E^Q[(\mathbb{S} - nK)_+ | A]] \\ &= \frac{e^{-rT}}{n} \left\{ \int_{-\infty}^{d_A} E^Q[(\mathbb{S} - nK)_+ | A = \lambda] dF_A(\lambda) \right. \\ &\quad \left. + \int_{d_A}^{+\infty} E^Q[\mathbb{S} - nK | A = \lambda] dF_A(\lambda) \right\}. \end{aligned} \quad (49)$$

The second term in equality (49) can be written in closed-form along similar lines as (42)–(44):

$$\begin{aligned} \frac{e^{-rT}}{n} \int_{d_A}^{+\infty} E^Q[\mathbb{S} | A = \lambda] dF_A(\lambda) - e^{-rT} K(1 - F_A(d_A)) \\ = \frac{e^{-rT}}{n} \sum_{i=0}^{n-1} S(0) e^{(r - \frac{1}{2}\sigma^2\rho_{T-i}^2)(T-i)} \int_{d_A}^{+\infty} e^{\rho_{T-i}\sigma\sqrt{T-i}\Phi^{-1}(v)} dF_A(\lambda) - e^{-rT} K(1 - \Phi(d_A^*)) \\ = \frac{S(0)}{n} \sum_{i=0}^{n-1} e^{-ri} \Phi(\rho_{T-i}\sigma\sqrt{T-i} - d_A^*) - e^{-rT} K\Phi(-d_A^*), \end{aligned} \quad (50)$$

where $d_A^* = (d_A - E^Q[A])/\sigma_A$ and $v = (\lambda - E^Q[A])/\sigma_A$.

In the first term of (49) we replace \mathbb{S} by \mathbb{S}^u in order to obtain an upper bound and apply (16) but now with an integral from zero to $\Phi(d_A^*)$:

$$\begin{aligned} \frac{e^{-rT}}{n} \int_{-\infty}^d E^Q[(\mathbb{S} - nK)_+ | A = \lambda] dF_A(\lambda) \\ \leq \frac{e^{-rT}}{n} \int_{-\infty}^d E^Q[(\mathbb{S}^u - nK)_+ | A = \lambda] dF_A(\lambda) \\ = \frac{e^{-rT}}{n} \int_0^{\Phi(d_A^*)} E^Q[(\mathbb{S}^u - nK)_+ | V = v] dv \\ = \frac{S(0)}{n} \sum_{i=0}^{n-1} e^{-ri} e^{-\frac{\sigma^2}{2}\rho_{T-i}^2(T-i)} \\ \quad \times \int_0^{\Phi(d_A^*)} e^{\rho_{T-i}\sigma\sqrt{T-i}\Phi^{-1}(v)} \Phi(\sqrt{1 - \rho_{T-i}^2}\sigma\sqrt{T-i} - \Phi^{-1}(F_{\mathbb{S}^u|V=v}(nK))) dv \\ \quad - e^{-rT} K \left(\Phi(d_A^*) - \int_0^{\Phi(d_A^*)} F_{\mathbb{S}^u|V=v}(nK) dv \right). \end{aligned} \quad (51)$$

Adding (50) and (51) we obtain (48). \square

Theorem 8. For any conditioning variable A satisfying the assumptions of Theorem 7,

$$\text{PECUB}A \leq \text{ICUB}A,$$

where $\text{PECUB}A$ and $\text{ICUB}A$ are defined by (48) and (16), respectively.

Proof. Recall that according to the assumption of Theorem 7 there exists d_A such that $A \geq d_A \Rightarrow S \geq nK$. Using this fact and by convex ordering of stop-loss premia of S and S^u we obtain

$$\begin{aligned}
 ne^{rT} \text{ICUB}_A &= \int_{-\infty}^{+\infty} E[(S^u - nK)_+ | A = \lambda] dF_A(\lambda) \\
 &= \int_{-\infty}^{d_A} E[(S^u - nK)_+ | A = \lambda] dF_A(\lambda) + \int_{d_A}^{+\infty} E[(S^u - nK)_+ | A = \lambda] dF_A(\lambda) \\
 &\geq \int_{-\infty}^{d_A} E[(S^u - nK)_+ | A = \lambda] dF_A(\lambda) + \int_{d_A}^{+\infty} E[(S - nK)_+ | A = \lambda] dF_A(\lambda) \\
 &= \int_{-\infty}^{d_A} E[(S^u - nK)_+ | A = \lambda] dF_A(\lambda) + \int_{d_A}^{+\infty} E[S - nK | A = \lambda] dF_A(\lambda) \\
 &= ne^{rT} \text{PECUB}_A. \quad \square
 \end{aligned}$$

We stress that for two distinct conditioning variables A_1 and A_2 it does not necessarily hold that $\text{PECUB}_{A_1} \leq \text{ICUB}_{A_2}$.

For the random variables A given by (13) and (14) we derived a d_A , see (47) and (46), and thus we can compute the new upper bound PECUB_A , cf. (48). Recall that these choices of A do not lead to the best improved comonotonic upper bound. The “best” choice is $A = B(T)$ for which we do not find the necessary d_A in this new upper bound. However, we expect that the contribution of the exact part (50) which is the second term in (49) will compensate for the somewhat lower quality of the S^u .

Finally, we note that the upper bound $C_A^{*,G}$ in [19] was derived for the special conditioning variable A given by (14), with the usage of an optimization algorithm to find the weights a_i such that their upper bound for the first term in (49), namely

$$\frac{e^{-rT}}{n} \sum_{i=0}^{n-1} \int_{-\infty}^{d_A} E^Q[(S(T-i) - a_i nK)_+ | A = \lambda] dF_A(\lambda),$$

is minimized. In fact, they introduce a second approximation by bounding this expression from above using a portfolio of call options, following the presentation in [22]. The expression obtained this way is then minimized with respect to the weights a_i . With our method, however, we directly have the explicit optimal solution of the original minimization problem, namely the optimal weights a_i for a given λ or v are:

$$\begin{aligned}
 a_i &= \frac{1}{nK} F_{S(T-i)|A=\lambda}^{-1}(F_{S^u|V=v}(nK)) \\
 &= \frac{S(0)}{nK} e^{(r-\frac{\sigma^2}{2})(T-i) + \rho_{T-i} \sigma \sqrt{T-i} \Phi^{-1}(v) + \sqrt{1-\rho_{T-i}^2} \sigma \sqrt{T-i} \Phi^{-1}(F_{S^u|V=v}(nK))}.
 \end{aligned}$$

In this sense, the partially exact/comonotonic upper bound improves their upper bound $C_A^{*,G}$, see Table 3 for numerical results.

2.4. General remarks

In this section we summarize some general remarks:

1. Denoting the price of a European-style discrete arithmetic Asian *put* option with exercise date T , n averaging dates and fixed strike price K by $AP(n, K, T)$, we find from the put-call parity at the present:

$$AC(n, K, T) - AP(n, K, T) = \frac{S(0)}{n} \frac{1 - e^{-rn}}{1 - e^{-r}} - e^{-rT} K. \quad (52)$$

Hence, we can derive bounds for the Asian put option from the bounds for the call. These bounds for the put option coincide with the bounds that are obtained by applying the theory of comonotonic bounds and the conditioning approach directly to Asian put options. This stems from the fact that the put-call parity also holds for these bounds.

2. Note that for numerical computations in (52), if n and T are expressed in days then r should be interpreted as a continuously compounded interest rate for one day which equals a continuously compounded interest rate for one year divided by the number of (trading) days per year.
3. The case of a continuous dividend yield δ can easily be dealt with by replacing the interest rate r by $r - \delta$.
4. When the number of averaging dates n equals 1, the Asian call option $AC(n, K, T)$ reduces to a European call option. It can be proven that in this case the upper and the lower bounds for the price of the Asian option both reduce to the Black and Scholes formula for the price of a European call option. For bounds based on a conditioning variable A this is true since for $n = 1$ we have that $A = \beta_0 B(T)$ while $\mathbb{S} = S(0) \exp((r - \frac{1}{2}\sigma^2)T + \sigma B(T))$ implying that $\rho_T = 1$, and thus that $\mathbb{S}^u = \mathbb{S}^\ell = \mathbb{S}$.
5. The lower and upper bounds are derived for forward starting Asian options but they can easily be adapted to hold for Asian options in progress. In this case $T - n + 1 \leq 0$ and only the prices of $S(1), \dots, S(T)$ remain random such that the price of the option is given by

$$\begin{aligned} AC(n, K, T) &= \frac{e^{-rT}}{n} E^Q \left[\left(\sum_{i=0}^{n-1} S(T-i) - nK \right)_+ \right] \\ &= \frac{e^{-rT}}{n} E^Q \left[\left(\sum_{i=0}^{T-1} S(T-i) - \left(nK - \sum_{i=T}^{n-1} S(T-i) \right) \right)_+ \right]. \end{aligned}$$

Thus substituting $nK - \sum_{i=T}^{n-1} S(T-i)$ for nK and summing for the average over i from zero to $T-1$ instead of $n-1$ the desired bounds follow.

6. The bounds can be extended to the case of deterministic volatility function $\sigma = \sigma(t)$ or $\sigma = \sigma(S(0), t)$ but are not applicable when we assume a stochastic volatility surface $\sigma = \sigma(S, t)$.

2.5. Numerical illustration

In this section we give a number of numerical examples in the Black and Scholes setting. We discuss our results and compare them to those found in the literature and to the Monte Carlo price. Further, we approximate \mathbb{S} by a lognormal distribution which is the closest in the Kullback–Leibler sense. We also measure the closeness of the lower and upper bounds in the distributional sense.

Table 1

Notations for lower and upper bounds used in Table 2 and Table 3

<i>lower bounds</i>	
LBB _T :	lower bound with $\Lambda = \sum_{k=1}^T W_k \stackrel{d}{=} B(T)$
LB FA:	lower bound with $\Lambda = \sum_{j=0}^{n-1} \exp[(r - \frac{\sigma^2}{2})(T - j)] B(T - j)$
LB GA:	lower bound with $\Lambda = (\ln \mathbb{G} - E\hat{Q}[\ln \mathbb{G}])/\sqrt{\text{var} \hat{Q}(\ln \mathbb{G})}$
<i>upper bounds</i>	
UBGA _d :	upper bound equal to lower bound LB GA plus $\varepsilon(d_{\text{GA}})e^{-rT}/n$
UBFA _d :	upper bound equal to lower bound LB FA plus $\varepsilon(d_{\text{FA}})e^{-rT}/n$
UB FA:	upper bound equal to lower bound LB FA plus constant $\varepsilon e^{-rT}/n$
UB GA:	upper bound equal to lower bound LB GA plus constant $\varepsilon e^{-rT}/n$
PECUB GA:	partially exact/comonotonic upper bound with $\Lambda = (\ln \mathbb{G} - E\hat{Q}[\ln \mathbb{G}])/\sqrt{\text{var} \hat{Q}(\ln \mathbb{G})}$
ICUBB _T :	improved comonotonic upper bound with $\Lambda = \sum_{k=1}^T W_k \stackrel{d}{=} B(T)$
UBB _T :	upper bound equal to lower bound LBB _T plus constant $\varepsilon e^{-rT}/n$

2.5.1. Comparing bounds

In this section we discuss our results and compare them with those of Jacques [14] where the distribution of the sum \mathbb{S} of lognormals, see (6), entering in the European-style discrete arithmetic Asian option was approximated by means of the lognormal (LN) and the inverse Gaussian (IG) distribution. For the comparison we also included the upper bounds based on the lower bounds, see Theorem 5 and 6. We show here one set of numerical experiments where we consider a forward starting European-style discrete arithmetic Asian call option with fixed strike having the same data as in the paper of Jacques [14]: an initial stock price $S(0) = 100$, a nominal annual (daily discretely compounded) interest rate of 9% per year (corresponding to a continuously compounded interest rate $r = \ln(1 + \frac{0.09}{365})$ per day¹ or 8.9989% per year), a maturity of 120 days and an averaging period n of 30 days. The values of the volatility σ are on annual basis. As a benchmark we included the price obtained via Monte Carlo simulation by adapting the control variate technique of Kemna and Vorst [16] to European-style discrete arithmetic Asian options. The number of simulated Monte Carlo paths was 10 000.

We use the following notations where Λ can be GA, FA or B_T : LBA for lower bound, PECUBA for partially exact/comonotonic upper bound, UBA for upper bound based on lower bound (cf. Theorem 5), and UBA_d for upper bound given by Theorem 6. Examples and other notations can be found in Table 1.

As we see from Table 2, the lower bounds LB FA and LB GA are equal up to five decimals. They both perform much better in comparison with Monte Carlo results than the lower bound LBB_T where we conditioned on $\Lambda = \sum_{k=1}^T W_k \stackrel{d}{=} B(T)$ (cf. (24)). The bad performance is due to the fact that $B(T)$ differs much from \mathbb{S} for n larger than one and hence $E^Q[\sqrt{\text{var} \hat{Q}(\mathbb{S} | B(T))}]$ is large, while for the Λ of

¹ In the paper of Jacques [14] this interest rate is reported and is used in our computations of the bounds. The actual computations in [14] were made with a continuously compounded interest rate of $\ln(1 + 0.09)/365$ per day, where 9% is an effective annual interest rate. Due to this inconsistency, we recomputed LN and IG approximations with the interest rate as mentioned in that paper.

Table 2
LN and IG approximations of Jacques [14] compared with our bounds

σ	K	LN	IG	MC ($SE \times 10^4$)	LB B_T	LB FA	LB GA	UB GA_d	UB FA_d	UB FA	PECUB GA	ICUB B_T	UB B_T

$T = 120$, $n = 30$, $r = \ln(1 + 0.09/365)$ daily, $S(0) = 100$, σ : yearly volatility, K : strike price, LN: lognormal approximation of a sum of lognormals, IG: inverse gaussian approximation of a sum of lognormals, MC: Monte Carlo price with its standard error (SE) based on 10 000 paths, the notations for the lower and upper bounds are given in Table 1.

(13) or (14) this term $E^Q[\sqrt{\text{var}^Q(\mathbb{S} | A)}]$ is very small because A and \mathbb{S} are very much alike. It seems that the relative difference between a lower bound and its upper-bound-counterpart increases with K . For the upper bounds UB FA and UB B_T this is clear, since for different values of K a same constant is added while the value of the lower bound is decreasing. The upper bound UB GA_d which is based on the lower bound LB GA plus a pricing error cf. (37)–(38) and (46), performs the best of all upper bounds considered. However, UB FA_d cf. (37)–(38) and (47), performs good as well. For this set of parameters, the values for the partially exact/comonotonic upper bound PECUB GA, cf. (48) and (46), are smaller than those for the improved comonotonic upper bound ICUB B_T but, as the results in Table 2 show for the case of A given by (14), they are not that good as we would have expected. Notice that we have included only PECUB GA in Table 2 since it was the best PECUB A upper bound for the two conditioning variables that we consider.

Comparing UB FA with UB FA_d , we note that making the error bound dependent on the strike price K has led to an improvement. Table 2 also reveals that in general the lognormal (LN) approximation as well as the inverse Gaussian (IG) approximation of Jacques [14] fall within the interval given by the best lower bound and the best upper bound. The exception is the lognormal approximation in case when $K = 110$ for $\sigma = 0.2$ and 0.3 , and the inverse Gaussian approximation in case when $K = 80$ for $\sigma = 0.2, 0.3$, and 0.4 (in those cases the prices are smaller than the (comonotonic) lower bounds LB FA and LB GA). Notice that the approximations of Jacques [14] (except of the cases mentioned above) are always higher than the respective Monte Carlo values, but nevertheless they all fall into the Monte Carlo price interval ($MC \pm SE$). Further, note that the precision of the simulated prices decreases as the volatility σ increases. The Monte Carlo approach systematically seems to underestimate the true price, especially for at- and out-of-the-money options for which the Monte Carlo price falls slightly below the lower bounds.

Conclusion 1. From Table 2 LB FA and LB GA perform equally well and are very close to the Monte Carlo values. The UB GA_d is the best upper bound for the parameters considered in this table.

2.5.2. The effect of the averaging period and of interest rates on the bounds

In this section we compare bounds over several averaging periods and for different interest rates. For different sets of parameters, we have computed the lower and the upper bounds together with the price obtained by Monte Carlo simulation.² The latter is based on generating 10 000 paths. This has been done in particular for four different options: the first with expiration date at time $T = 120$ and 30 averaging days, the second with expiration at time $T = 60$ and 30 averaging days, the third one with again expiration time $T = 120$ but only 10 averaging days, and as the last one we considered the case where averaging was done over the whole period of 120 days. In all cases we considered the following four strike prices K : 80, 90, 100 and 110, three values (0.2, 0.3 and 0.4) for the volatility σ , and the two different flat continuously compounded risk-free interest rates r : 5% and 9% yearly. The initial stock price was fixed at $S(0) = 100$.

The absolute and relative differences between the best upper and lower bound increase with the volatility and with the strike price, but decrease with the interest rate. The results further suggest that all intervals are sharper for options that are in-the-money. For fixed maturity, the length of the intervals reduces with

² The tables with the results discussed in this paragraph are available from Liinev [18].

the number of averaging dates. However for a fixed averaging period the effect of the maturity date seems to be less clear.

Conclusion 2. *The difference between the lower bounds LB GA and LB FA is overall practically zero. The upper bound UB GA_d is in general the best but for example when $r = 0.05$, $K = 100$ and $\sigma = 0.4$, UB FA_d turns out to be smaller than UB GA_d.*

2.5.3. Comparison of lower and upper bounds as in [19] with our bounds

In this section we use the data from Nielsen and Sandmann [19] in order to compare their different upper bounds with our results. They give as input data: $\sigma = 0.25$, $r = 0.04$, $S(0) = 100$, $T = 3$ years. Note that they use price averaging over the whole period ($n = 3$ years) where averaging takes place each month (in the previous sections the averaging was done daily).

The first column of Table 3 shows the selection of strike prices from Nielsen and Sandmann [19]. In addition to the strike prices used in the above sections we also included $K = 50$ and 200 as examples of extreme in- and out-of-the-money options.

The bounds LB GA, UB GA and UB GA_d in Table 3 were reported in [19] and we recall that these three bounds are the special cases of the more general bounds LB \mathcal{A} , UB \mathcal{A} and UB \mathcal{A}_d , respectively. Nielsen and Sandmann [19] also derive another upper bound $C_A^{u,G}$ which depends on coefficients a_i satisfying $\sum_{i=1}^n a_i = 1$. The last three columns in Table 3 show the bounds $C_A^{u,G}$ for different choices of coefficients a_i . The columns labelled as $C_A^{*,G}$ and $C_A^{N,G}$ are computed for the choice of $a_i = a_i^*$ (special choice by Nielsen and Sandmann) and $a_i = \frac{1}{n}$, respectively. The column $C_A^{**,G}$ presents the results for the optimal sequence of the weights a_i in relation to the $C_A^{u,G}$ bound (i.e. the sequence which minimizes the upper bound $C_A^{u,G}$). From this table it is clear that the PECUB GA indeed improves $C_A^{**,G}$ as explained in Section 2.3.

We note again that the partially exact/comonotonic upper bound PECUB GA is smaller and thus better than the improved comonotonic upper bound ICUB B_T for strike prices in the range 50–150 (not all values are reported in Table 3), but for deeply out-of-the-money options there is a switch and ICUB B_T becomes better and even for $K = 200$ outperforms all other the upper bounds including the choices of Nielsen and Sandmann. Note that this is an example of the case when for two distinct conditioning variables \mathcal{A}_1 and \mathcal{A}_2 it does not follow that $\text{PECUB } \mathcal{A}_1 \leq \text{ICUB } \mathcal{A}_2$.

Conclusion 3. *We can conclude that the best upper bound is again given by UB GA_d. Notice also that the lower bounds LB FA and LB GA are very close and equal up to two decimals.*

2.5.4. Distributional distance between the bounds and lognormal approximation of \mathbb{S}

As already mentioned, the sum of lognormal random variables is not lognormally distributed. However, in practice it is often claimed to be approximately lognormal. In this section we aim to quantify the distance between the distribution of $\mathbb{S} = \sum_{i=1}^n X_i$, (7), which is a sum of lognormal random variables, and the lognormal family of distributions by means of the so-called Kullback–Leibler information. We also use the Hellinger distance in order to measure the closeness of the derived lower and upper bounds. This section uses the ideas from Brigo and Lilev [5] and we refer to Lilev [18] for more details. See also Brigo et al. [6] in the context of basket options.

Firstly, note that it is possible to calculate the Kullback–Leibler distance (KLI) of the distribution of the sum \mathbb{S} from the lognormal family of distributions \mathcal{L} in the following way

$$\begin{aligned} \text{KLI}(p(x), \mathcal{L}) = E_p[\ln p(x)] + \frac{1}{2} + E_p \left[\ln \left(\frac{x}{S(0)} \right) \right] \\ + \frac{1}{2} \ln \left(2\pi S(0)^2 \left[E_p \left[\ln^2 \left(\frac{x}{S(0)} \right) \right] - \left(E_p \left[\ln \left(\frac{x}{S(0)} \right) \right] \right)^2 \right] \right), \end{aligned} \quad (53)$$

where $p(x)$ denotes the density function of \mathbb{S} , and $E_p[\phi(x)] = \int \phi(x)p(x) dx$. This distance is readily computed, once one has an estimate of the true \mathbb{S} density and of its first two log-moments. Distance (53) can be interpreted as the distance of the distribution of \mathbb{S} from the closest log-normal distribution in Kullback–Leibler sense. The latter is the distribution which shares the same log-moments $E_p[(\ln(\cdot))^i]$, $i = 1, 2$ with the distribution of \mathbb{S} .

This provides an alternative way to the lognormal approximation of Jacques [14] in order to compute the price of the Asian call option $\text{AC}(n, K, T)$. Namely, we can estimate the parameters of the closest lognormal distribution based on the simulated \mathbb{S} , and then apply the standard Black and Scholes technique in order to find the price. This method is considerably easier to implement than that of Jacques [14]. However, to obtain a correct price approximation, more simulations are needed than for the usual Monte-Carlo price estimate.

In Table 4 we present the results obtained in evaluating the Kullback–Leibler distance for the sum of lognormals \mathbb{S} through a standard Monte Carlo method with 10 000 antithetic paths, for the parameters in Table 2. In the brackets we show the sample standard errors (SE) for both quantities. In order to have an idea for what it means to have a KLI distance of about 0.003 between two distributions, we may resort to the KLI distance of two lognormals, which can be easily computed analytically. It appears that we find a KLI distance comparable in size to our distances below if we consider for example two lognormal densities with the same mean but different standard deviations. Then a KLI distance of approximately 0.003 amounts to a percentage difference in standard deviations of about 0.29%. This gives a feeling for the size of the distributional discrepancy our distance implies.

In Table 5 we show the corresponding lognormal price approximation (for the respective Monte Carlo values we refer to Table 2). These values seem to indicate that this method underestimates the price. This indicates that even the optimal lognormal distribution (in KLI sense) does not attribute enough weight to the upper tail.

In Table 6 we display the Hellinger distances HD between the densities p_1 of \mathbb{S}^ℓ , (35), when the conditioning variable A is given by (13) (hereafter denoted as $\mathbb{S}_{\text{FA}}^\ell$), and p_c of the comonotonic sum \mathbb{S}^c ,

Table 5

Price approximation based on the closest lognormal distribution in Kullback–Leibler sense

K	$\sigma = 0.2$	$\sigma = 0.3$	$\sigma = 0.4$
80	22.00133	22.30572	23.02679
90	12.75699	13.91766	15.41261
100	5.51592	7.52534	9.55076
110	1.64775	3.50850	5.50423

Table 6

Hellinger distance between comonotonic lower and upper bound of \mathbb{S}

σ	$\text{HD}(\mathbb{S}_{\text{FA}}^{\ell}; \mathbb{S}^c)$
0.2	0.001756845
0.3	0.001831938
0.4	0.001949698

defined as

$$\text{HD}(\mathbb{S}_{\text{FA}}^{\ell}; \mathbb{S}^c) := 2 - 2 \int \sqrt{p_{\ell}(x)p_c(x)} \, dx.$$

It appears that increasing the volatility σ the densities tend to move further away from each other.

We also computed the distance between the densities of $\mathbb{S}_{\text{FA}}^{\ell}$ and of $\mathbb{S}_{\text{GA}}^{\ell}$ which is \mathbb{S}^{ℓ} with conditioning variable \mathcal{A} (14). This distance was found to be of the magnitude of 10^{-13} , and also increasing with increasing σ .

2.6. Hedging the fixed strike Asian option

Hedging is an important concept for managing risks in the market. Most traders use quite sophisticated hedging schemes which involve calculating several “measures” in order to characterize risk exposure. These measures are referred to as “Greek letters”, or “Greeks”. Each Greek measures a different aspect of the risk in an option position. Delta represents the sensitivity with respect to $S(0)$, the initial value of the underlying asset. It is defined as a rate of change of the option price w.r.t. the price of the underlying asset. Gamma of a portfolio of derivatives is a rate of change of the portfolio’s Delta w.r.t. the asset price. Vega characterizes the rate of change of the value of the portfolio w.r.t. the volatility of the underlying asset.

In this section we show that from the analytical expressions in terms of Black and Scholes prices for the lower and the upper bounds we can easily obtain the hedging Greeks which are summarized by the following proposition. Note, however, that these expressions for the Greeks do not represent the bounds for the hedging parameters. Instead, they can be considered as an approximation to the hedging Greeks. Nielsen and Sandmann [19] also derived the Greeks for their bounds, noticing that this approximation was quite good in numerical examples.

Table 7
Delta, Gamma and Vega for bounds

Bound	Greeks
<i>Delta (Δ)</i>	
LBA	$\sum_{i=0}^{n-1} \frac{e^{-ri}}{n} \Phi(\rho_{T-i} \sigma \sqrt{T-i} - \Phi^{-1}(F_{\mathbb{S}^{\ell}}(nK)))$
ICUBA	$\int_0^1 I_2(v) dv$
PECUBA	$\sum_{i=0}^{n-1} \frac{e^{-ri}}{n} \Phi(\rho_{T-i} \sigma \sqrt{T-i} - d_A^*) + \int_0^{\Phi(d_A^*)} I_2(v) dv + [\chi(d_A^*) + I_1(\Phi(d_A^*))\varphi(d_A^*)] \frac{\partial d_A^*}{\partial S(0)}$
UBA	$\Delta_{LBA} + \frac{e^{-rT}}{2n} \int_0^1 \sqrt{q(v)} dv$
UBA _d	$\Delta_{LBA} + g(d_A^*)[1 + \eta(d_A^*)]$
<i>Gamma (Γ)</i>	
LBA	$e^{-rT} n [\frac{K}{S(0)}]^2 \varphi(\Phi^{-1}(F_{\mathbb{S}^{\ell}}(nK))) [\sum_{i=0}^{n-1} \tilde{K}_i \sigma \rho_{T-i} \sqrt{T-i}]^{-1}$
ICUBA	$e^{-rT} n [\frac{K}{S(0)}]^2 \int_0^1 \varphi(\Phi^{-1}(F_{\mathbb{S}^u V=v}(nK))) [\sum_{i=0}^{n-1} \tilde{K}_i(v) p_i(v) e^{-r(T-i)} \sigma \sqrt{1 - \rho_{T-i}^2} \sqrt{T-i}]^{-1} dv$
PECUBA	$[-\frac{e^{-rT}}{n} \sum_{i=0}^{n-1} p_i(\Phi(d_A^*)) + 2I_2(\Phi(d_A^*)) + \frac{\partial \chi(d_A^*)}{\partial S(0)}] \varphi(d_A^*) \frac{\partial d_A^*}{\partial S(0)} + \chi(d_A^*) \frac{\partial^2 d_A^*}{\partial S(0)^2} + \gamma(d_A^*) I_1(\Phi(d_A^*))$ $+ e^{-rT} n [\frac{K}{S(0)}]^2 \int_0^{\Phi(d_A^*)} \varphi(\Phi^{-1}(F_{\mathbb{S}^u V=v}(nK))) [\sum_{i=0}^{n-1} \tilde{K}_i(v) p_i(v) e^{-r(T-i)} \sigma \sqrt{1 - \rho_{T-i}^2} \sqrt{T-i}]^{-1} dv$
UBA	Γ_{LBA}
UBA _d	$\Gamma_{LBA} + \frac{1}{2} g(d_A^*)[(1 + \eta(d_A^*))\eta(d_A^*) + \frac{\partial \eta(d_A^*)}{\partial d_A^*}] \frac{\partial d_A^*}{\partial S(0)}$
<i>Vega (\mathcal{V})</i>	
LBA	$\frac{e^{-rT}}{n} [\sum_{i=0}^{n-1} \tilde{K}_i \rho_{T-i} \sqrt{T-i}] \varphi(\Phi^{-1}(F_{\mathbb{S}^{\ell}}(nK)))$
ICUBA	$\int_0^1 \frac{\partial I_1(v)}{\partial \sigma} dv$
PECUBA	$[\chi(d_A^*) + I_1(\Phi(d_A^*))\varphi(d_A^*)] \frac{\partial d_A^*}{\partial \sigma} + \frac{e^{-rT}}{n} S(0) \varphi(d_A^*) \sum_{i=0}^{n-1} p_i(\Phi(d_A^*)) \rho_{T-i} \sqrt{T-i} + \int_0^{\Phi(d_A^*)} \frac{\partial I_1(v)}{\partial \sigma} dv$
UBA	$\mathcal{V}_{LBA} + \frac{e^{-rT}}{4n} S(0) \int_0^1 \frac{1}{\sqrt{q(v)}} \frac{\partial q(v)}{\partial \sigma} dv$
UBA _d	$\mathcal{V}_{LBA} + \frac{S(0)}{2} g(d_A^*) \zeta(d_A^*) \frac{\partial d_A^*}{\partial \sigma}$

Notations:

$$\begin{aligned}
 p_i(v) &= e^{(r - \frac{\sigma^2}{2} \rho_{T-i}^2)(T-i)} e^{\rho_{T-i} \sigma \sqrt{T-i} \Phi^{-1}(v)}, & g(d_A^*) &= \frac{e^{-rT}}{2n} \Phi(d_A^*)^{1/2} h(d_A^*)^{1/2}, \\
 I_1(v) &= \frac{1}{n} \sum_{i=0}^{n-1} \frac{p_i(v)}{e^{r(T-i)}} [e^{-ri} S(0) \Phi(d_{1,i}(v)) - e^{-rT} \tilde{K}_i(v) \Phi(d_{2,i}(v))], & \zeta(d_A^*) &= \frac{\varphi(d_A^*)}{\Phi(d_A^*)} + \frac{1}{h(d_A^*)} \frac{\partial h(d_A^*)}{\partial d_A^*}, \\
 I_2(v) &= \frac{\partial I_1(v)}{\partial S(0)} = \frac{e^{-rT}}{n} \sum_{i=0}^{n-1} p_i(v) \Phi(d_{1,i}(v)), & \eta(d_A^*) &= \frac{S(0)}{2} \zeta(d_A^*) \frac{\partial d_A^*}{\partial S(0)}, \\
 c_{ij} &= e^{\sigma^2(\min(T-i, T-j) - \rho_{T-i} \rho_{T-j} \sqrt{T-i} \sqrt{T-j})}, & \gamma(d_A^*) &= \varphi(d_A^*) \left[-d_A^* \left(\frac{\partial d_A^*}{\partial S(0)} \right)^2 + \frac{\partial^2 d_A^*}{\partial S(0)^2} \right], \\
 q_{ij} &= e^{r(2T-i-j) + \sigma^2 \rho_{T-i} \rho_{T-j} \sqrt{T-i} \sqrt{T-j} (c_{ij} - 1)}, & \chi(d_A^*) &= e^{-rT} \varphi(d_A^*) \left[K - \frac{S(0)}{n} \sum_{i=0}^{n-1} p_i(\Phi(d_A^*)) \right], \\
 h(d_A^*) &= \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} q_{ij} \Phi(d_A^*) - \sigma(\rho_{T-i} \sqrt{T-i} + \rho_{T-j} \sqrt{T-j}), & q(v) &= \frac{\text{var } Q(\mathbb{S}|A)}{S(0)^2} = \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} p_i(v) p_j(v) c_{ij} - [\sum_{i=0}^{n-1} p_i(v)]^2
 \end{aligned}$$

Proposition 1. The Delta, Gamma and Vega positions of bounds (9), (16), (48), (27), and (37) are given by the expressions in Table 7.

The proof for obtaining the hedging Greeks is a straightforward application of partial differentiation of the combinations of Black and Scholes type prices that we found for the bounds (cf. Theorems 2 and 4).

In the next section we discuss different methods for pricing European-style discrete arithmetic Asian options with floating strike through the bounds developed in previous sections.

3. Floating strike Asian options in a Black and Scholes settings

By arbitrage arguments, the price at current time $t = 0$ of a floating strike Asian put option with percentage β is given by

$$\text{APF}(n, \beta, T) = \frac{e^{-rT}}{n} E^Q \left[\left(\sum_{i=0}^{n-1} S(T-i) - n\beta S(T) \right)_+ \right]$$

under the risk-neutral probability measure Q . In the Black and Scholes model, the following change of measure leads to results dealt with in Section 2. Let us define the probability \tilde{Q} equivalent to Q by the Radon–Nikodym derivative

$$\frac{d\tilde{Q}}{dQ} = \frac{S(T)}{S(0)e^{rT}} = \exp \left(-\frac{\sigma^2}{2} T + \sigma B(T) \right). \quad (54)$$

Under this probability \tilde{Q} , $\tilde{B}(t) = B(t) - \sigma t$ is a Brownian motion and therefore, the dynamics of the share under \tilde{Q} are given by

$$\frac{dS(t)}{S(t)} = (r + \sigma^2) dt + \sigma d\tilde{B}(t). \quad (55)$$

Let us exemplarily consider the case of a forward starting floating strike Asian put option with $T - n + 1 > 0$.

Using the probability \tilde{Q} , the corresponding option price is given by

$$\text{APF}(n, \beta, T) = \frac{S(0)}{n} E^{\tilde{Q}} \left[\left(\frac{\sum_{i=0}^{n-1} S(T-i)}{S(T)} - \beta n \right)_+ \right].$$

From this formula, one can conjecture that a floating strike Asian put option can be interpreted as a fixed strike Asian call with strike price $\beta S(0)$. Henderson and Wojakowski [13] have obtained symmetry results between the floating and fixed strike Asian options in the forward starting case of continuous averaging. They considered the Black and Scholes dynamics for the underlying asset with a continuous dividend yield δ . In Section 3.1, we prove similar results in case of the European-style discrete arithmetic Asian options. The symmetry results become very useful for transferring knowledge about one type of an option to another. However, there does not exist such a symmetry relation for the options ‘in progress’.

3.1. Symmetry results for arithmetic Asian options

In order to derive the similar results to Henderson and Wojakowski [13] in case of discrete averaging, we introduce some generalized notation. For the fixed strike Asian call option we use the notation

$$\text{AC}(x_1, x_2, x_3, x_4, x_5, x_6, x_7),$$

where x_1 is the strike price, x_2 the initial value of the process $(S(t))_{t \geq 0}$, x_3 the risk-free interest rate, x_4 the dividend yield, x_5 the option maturity, x_6 the number of averaging terms, and x_7 the starting date of averaging.

Analogously, for a put option we set $\text{AP}(x_1, x_2, x_3, x_4, x_5, x_6, x_7)$. For example, $\text{AP}(K, S(0), r, \delta, T, n, T - n + 1)$ denotes the Asian put option with fixed strike price K and maturity date T which is

forward starting with n terms and with the first term being $S(T - n + 1)$, where $(S(t))_{t \geq 0}$ denotes as usual a Black and Scholes process with initial value $S(0)$ and with dividend yield δ . The short-term constant interest rate equals r .

For floating strike options, we introduce a similar slightly modified notation. Namely, by

$$\text{ACF}(y_1, y_2, y_3, y_4, y_5, y_6, y_7)$$

we denote the floating strike Asian call option with y_1 the initial value of the process $(S(t))_{t \geq 0}$, y_2 the percentage, y_3 the risk-free interest rate, y_4 the dividend yield, y_5 the option maturity, y_6 the number of averaging terms in the strike, and y_7 the starting date of averaging.

For example, $\text{ACF}(S(0), K/S(0), \delta, r, T, n, 0)$ denotes the European-style floating strike Asian call option with percentage $K/S(0)$ and maturity date T which is forward starting with n terms and with the first term being $S(0)$, where $(S(t))_{t \geq 0}$ denotes as usual a Black and Scholes process with initial value $S(0)$ and with dividend yield r . The constant short-term interest rate is equal to δ . Analogously, for a floating strike put option we set $\text{APF}(y_1, y_2, y_3, y_4, y_5, y_6, y_7)$.

Using these notations, we obtain the following symmetry results, which are proved in Appendix B.

Theorem 9.

$$\begin{aligned} \text{AP}(K, S(0), r, \delta, T, n, T - n + 1) &= \text{ACF}\left(S(0), \frac{K}{S(0)}, \delta, r, T, n, 0\right) \\ \text{ACF}(S(0), \beta, r, \delta, T, n, T - n + 1) &= \text{AP}(\beta S(0), S(0), \delta, r, T, n, 0) \end{aligned}$$

and

$$\begin{aligned} \text{AC}(K, S(0), r, \delta, T, n, T - n + 1) &= \text{APF}\left(S(0), \frac{K}{S(0)}, \delta, r, T, n, 0\right) \\ \text{APF}(S(0), \beta, r, \delta, T, n, T - n + 1) &= \text{AC}(\beta S(0), S(0), \delta, r, T, n, 0). \end{aligned}$$

From the equalities above it is clear that by using the results of Section 2, one can obtain bounds for a floating strike Asian option through the bounds for a fixed strike Asian option. Note that the interest rate and the dividend yield have switched their roles when going from a floating to a fixed strike Asian option or vice versa.

3.2. Direct approach

In what follows we show that, instead of using symmetry, we can directly derive bounds for the floating strike Asian options. We also stress that these bounds can manage both ‘in progress’ and forward-starting floating strike Asian options as opposed to the approach using symmetry. Writing down the formulae for $S(T - i)$ and $S(T)$ in the Black and Scholes setting leads to

$$\mathbb{S} = \frac{\sum_{i=0}^{n-1} S(T - i)}{S(T)} = \sum_{i=0}^{n-1} e^{-(r + \frac{\sigma^2}{2})i + \sigma(\tilde{B}(T-i) - \tilde{B}(T))} = : \sum_{i=0}^{n-1} \alpha_i e^{Y_i}$$

with $\alpha_i = e^{-(r+\frac{\sigma^2}{2})i}$ and with $Y_i = \sigma(\tilde{B}(T-i) - \tilde{B}(T))$ a normally distributed random variable with mean $E^{\tilde{Q}}[Y_i] = 0$ and variance $\sigma_{Y_i}^2 = i\sigma^2$. Note that $\alpha_0 e^{Y_0}$ is in fact a constant. Clearly \mathbb{S} is a sum of lognormal variables and thus we can apply the results of Section 2.

Denoting the price of an European-style discrete arithmetic floating strike Asian *call* option with exercise date T , n averaging dates and percentage β by

$$\text{ACF}(n, \beta, T) = \frac{e^{-rT}}{n} E^{\tilde{Q}} \left[\left(n\beta S(T) - \sum_{i=0}^{n-1} S(T-i) \right)_+ \right],$$

we find from the put-call parity at the present:

$$\text{APF}(n, \beta, T) - \text{ACF}(n, \beta, T) = \frac{S(0)}{n} \frac{1 - e^{-rn}}{1 - e^{-r}} - \beta S(0). \quad (56)$$

Hence, we can derive bounds for the Asian floating strike call option from the bounds for the put.

In the remaining of the section, we only work out in detail the forward starting case as the ‘in progress’ case can be dealt with in a similar way.

3.2.1. Lower bound

In order to obtain a lower bound of good quality for the forward starting Asian option, we consider as conditioning variable a normal random variable \mathcal{A} which is as much alike as \mathbb{S} . Inspired by the choice for the fixed case, we take

$$\mathcal{A} = \sum_{i=0}^{n-1} \beta_i (\tilde{B}(T-i) - \tilde{B}(T)) \quad (57)$$

with some positive real numbers β_i . In particular for $\beta_i = e^{-(r+\frac{\sigma^2}{2})i}$ we find the first-order approximation of \mathbb{S} . If β_i equals $1/\sqrt{\frac{1}{3}n^3 - \frac{1}{2}n^2 + \frac{1}{6}n}$ for all i , then $\mathcal{A} = (\ln \mathbb{G} - E^{\tilde{Q}}[\ln \mathbb{G}])/\sqrt{\text{var}^{\tilde{Q}}[\ln \mathbb{G}]}$ is the standardized logarithm of the geometric average \mathbb{G} :

$$\mathbb{G} = \left(\prod_{i=0}^{n-1} \frac{S(T-i)}{S(T)} \right)^{1/n} = \left(\prod_{i=0}^{n-1} \exp \left[- \left(r + \frac{\sigma^2}{2} \right) i + \sigma(\tilde{B}(T-i) - \tilde{B}(T)) \right] \right)^{1/n}, \quad (58)$$

with

$$E^{\tilde{Q}}[\ln \mathbb{G}] = - \left(r + \frac{\sigma^2}{2} \right) \frac{n-1}{2}$$

$$\text{var}^{\tilde{Q}}[\ln \mathbb{G}] = \frac{\sigma^2}{n^2} \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} \min(i, j) = \frac{\sigma^2}{n^2} \left(\frac{1}{3} n^3 - \frac{1}{2} n^2 + \frac{1}{6} n \right).$$

This choice of \mathcal{A} is similar to the choice (14) of Nielsen and Sandmann [19] in the fixed strike setting.

For general β_i , we have that $Y_i \mid \Lambda = \lambda$ is normally distributed with mean $r_i \frac{\sigma\sqrt{i}}{\sigma_A} \lambda$ and variance $\sigma_{Y_i}^2 (1 - r_i^2)$ where $r_0 = 0$ and for $i \geq 1$

$$r_i = \frac{\text{cov}(\tilde{B}(T-i) - \tilde{B}(T), \Lambda)}{\sqrt{i}\sigma_A} = \frac{\sum_{j=0}^{n-1} \beta_j \min(i, j)}{\sqrt{i} \sqrt{\sum_{i=0}^{n-1} \sum_{j=0}^{n-1} \beta_i \beta_j \min(i, j)}}. \quad (59)$$

For both choices of Λ that we consider, these correlations r_i are positive. We thus find analogously to Theorem 1 the following lower bound for the price of the forward starting Asian floating put option:

$$\text{APF}(n, \beta, T) \geq \frac{S(0)}{n} \sum_{i=0}^{n-1} e^{-r_i} \Phi[\sigma r_i \sqrt{i} - \Phi^{-1}(F_{\mathbb{S}^\ell}(n\beta))] - S(0)\beta(1 - F_{\mathbb{S}^\ell}(n\beta)),$$

where $F_{\mathbb{S}^\ell}(n\beta)$ is obtained from

$$\sum_{i=0}^{n-1} \exp \left[- \left(r + \frac{r_i^2 \sigma^2}{2} \right) i + r_i \sigma \sqrt{i} \Phi^{-1}(F_{\mathbb{S}^\ell}(n\beta)) \right] = n\beta.$$

3.2.2. Improved comonotonic upper bound

Analogously to the case of the improved comonotonic upper bound for the Asian fixed strike, we have found that also in the Asian floating strike case, the conditioning variable

$$\Lambda = - \sum_{k=1}^T W_k, \quad \text{with } W_k \text{ i.i.d. } N(0, 1) \text{ such that } \tilde{B}(T-i) \stackrel{d}{=} \sum_{k=1}^{T-i} W_k, \quad i = 0, \dots, n-1,$$

leads to a sharper upper bound than other choices, for example the conditioning variable in the lower bound.

The theory of comonotonicity (see (23) and (21)) then leads to the following upper bound:

$$\begin{aligned} & \frac{S(0)}{n} E \tilde{Q}[(\mathbb{S}^u - n\beta)_+] \\ &= \frac{S(0)}{n} \sum_{i=0}^{n-1} e^{-(r + \frac{\sigma^2}{2} r_i^2) i} \int_0^1 e^{r_i \sigma \sqrt{i} \Phi^{-1}(v)} \Phi \left(\sqrt{1 - r_i^2} \sigma \sqrt{i} - \Phi^{-1}(F_{\mathbb{S}^u|V=v}(n\beta)) \right) dv \\ & \quad - S(0)\beta(1 - F_{\mathbb{S}^u}(n\beta)) \end{aligned}$$

with the correlations given by $r_i = \sqrt{i/T}$, $i = 1, \dots, n-1$ and $r_0 = 0$. Invoking (19)–(20), the conditional distribution $F_{\mathbb{S}^u|V=v}(x)$ and the cdf of \mathbb{S}^u can be obtained.

3.2.3. Bounds based on the Rogers and Shi approach

By a similar reasoning as in Section 2.2, it is easy to derive an upper bound based on the lower bound by following the ideas of Rogers and Shi [21] and Nielsen and Sandmann [19]. Indeed, by using our conditioning variable Λ given by (57), we obtain

$$\text{APF}(n, \beta, T) \leq \frac{S(0)}{n} \{E \tilde{Q}[(\mathbb{S}^\ell - n\beta)_+] + \varepsilon(d_\Lambda)\},$$

where d_A is such that $\mathbb{S} \geq n\beta$ if $A \geq d_A$ and with

$$\varepsilon(d_A) = \frac{1}{2} \{\Phi(d_A^*)\}^{1/2} \times \left\{ \sum_{i=0}^{n-1} \sum_{j=0}^{n-1} e^{-r(i+j) + \sigma^2 r_i r_j \sqrt{i} \sqrt{j}} \Phi(d_A^* - \sigma(r_i \sqrt{i} + r_j \sqrt{j})) (e^{\sigma^2(\min(i,j) - r_i r_j \sqrt{i} \sqrt{j})} - 1) \right\}^{1/2},$$

where $d_A^* = (d_A - E\tilde{Q}[A])/\sigma_A$ and with correlations r_i defined in (59).

In particular for the linear transformation of the first order approximation (FA) of \mathbb{S} , namely $A = \sum_{i=0}^{n-1} \beta_i (\tilde{B}(T-i) - \tilde{B}(T))$ with $\beta_i = e^{-(r+\frac{\sigma^2}{2})i}$, one gets

$$\tilde{d}_{FA} = \frac{n\beta - \sum_{i=0}^{n-1} e^{-(r+\frac{\sigma^2}{2})i}}{\sigma}.$$

For $\beta_i = \frac{\sigma}{n}(1/\sqrt{\text{var}\tilde{Q}[\ln \mathbb{G}]})$ with the geometric average (GA) \mathbb{G} defined in (58), A equals the standardized logarithm of the geometric average and the corresponding d_A equals

$$\tilde{d}_{GA} = \frac{\ln(\beta) + (r + \frac{\sigma^2}{2})(n-1)/2}{\frac{\sigma}{n}\sqrt{\frac{1}{3}n^3 - \frac{1}{2}n^2 + \frac{1}{6}n}}.$$

Notice also, that analogously to Theorem 5 one can obtain an upper bound for $\text{APF}(n, \beta, T)$ in terms of a constant error ε .

3.2.4. Partially exact/comonotonic upper bound

Along similar lines as in Section 2.2.3, we can derive a partially exact/comonotonic upper bound by recalling that for some normally distributed variable A there exists a d_A such that $A \geq d_A$ implies $\mathbb{S} \geq n\beta$:

$$\begin{aligned} \text{APF}(n, \beta, T) &\leq \frac{S(0)}{n} \sum_{i=0}^{n-1} e^{-r_i} \Phi(r_i \sigma \sqrt{i} - d_A^*) - S(0) \beta \Phi(-d_A^*) \\ &\quad + \frac{S(0)}{n} \sum_{i=0}^{n-1} e^{-(r+\frac{\sigma^2}{2}r_i^2)i} \int_0^{\Phi(d_A^*)} e^{r_i \sigma \sqrt{i} \Phi^{-1}(v)} \Phi(\sqrt{1-r_i^2} \sigma \sqrt{i} - \Phi^{-1}(F_{\mathbb{S}^u|V=v}(n\beta))) dv \\ &\quad - S(0) \beta \left(\Phi(d_A^*) - \int_0^{\Phi(d_A^*)} F_{\mathbb{S}^u|V=v}(n\beta) dv \right), \end{aligned}$$

where $d_A^* = (d_A - E\tilde{Q}[A])/\sigma_A$ and $v = (\lambda - E\tilde{Q}[A])/\sigma_A$.

The first two terms of the upper bound are composing the exact part of $\frac{S(0)}{n} E\tilde{Q}[(\mathbb{S} - n\beta)_+]$, while the last two terms define the improved comonotonic upper bound for the remaining part of it.

3.3. Numerical illustration

In this section we shall give a numerical example of a floating strike Asian put option.

Table 8
Comparing bounds for a floating strike Asian put option

$T = 120, n = 30, \sigma$: yearly volatility, β : percentage, $S(0) = 100$;

MC: Monte Carlo price together with its standard error (SE) based on 10 000 paths;

LB FA: lower bound with $\Lambda = \sum_{i=0}^{n-1} e^{-(r+\frac{\sigma^2}{2})i} (\tilde{B}(T-i) - \tilde{B}(T))$;

LB GA: lower bound with $\Lambda = (\ln \mathbb{G} - E\tilde{Q}[\ln \mathbb{G}])/\sqrt{\text{var}\tilde{Q}(\ln \mathbb{G})}$;

UB GA_d: upper bound equal to lower bound LB GA plus $\varepsilon(\tilde{d}_{\text{GA}})S(0)/n$;

UB FA_d: upper bound equal to lower bound LB FA plus $\varepsilon(\tilde{d}_{\text{FA}})S(0)/n$;

UB FA: upper bound equal to lower bound LB FA plus constant $\varepsilon S(0)/n$;

PECUB GA: partially exact/comonotonic upper bound with $\Lambda = (\ln \mathbb{G} - E\tilde{Q}[\ln \mathbb{G}])/\sqrt{\text{var}\tilde{Q}(\ln \mathbb{G})}$;

ICUB B_T: improved comonotonic upper bound with $\Lambda = -\sum_{k=1}^T W_k \stackrel{d}{=} -\tilde{B}(T)$.

In Table 8 we display different lower and upper bounds for a floating strike Asian put option with an initial stock price $S(0) = 100$, a maturity of 120 days and an averaging period n of 30 days. The choices for volatility and risk-free interest rate are the same as in Section 2.5.2. The percentage β is chosen so that

$\beta S(0)$ corresponds to the respective strike K in Section 2.5.2. We obtained Monte Carlo price estimates (based on 10 000 simulated paths) by adapting the Kemna and Vorst [16] control variate technique. Indeed, by applying the change of measure (54), we can interpret a floating strike Asian put option as a fixed strike Asian call option with strike price $\beta S(0)$. Hence we can simulate the dynamics of the stock price according to (55), and use the geometric average \mathbb{G} given by (58) as our control variate.

Note that by using the put-call parity result (56) one can easily obtain the price for the floating strike Asian call option. For example, consider the entry in Table 8 with $\beta=1.0$, $\sigma=0.2$, and $r=0.05$. By applying (56), we obtain that $\text{LB FA} = 1.387410$, $\text{LB GA} = 1.387411$, $\text{UB GA}_d = 1.388847$, $\text{UB FA}_d = 1.388792$, $\text{PECUB GA} = 1.557532$, and $\text{ICUB } B_T = 1.575395$.

We observe similar behaviour of the lower and upper bounds as for the fixed strike Asian call option apart from some interesting particular cases:

1. For $\sigma = 0.2, 0.3, 0.4$ and $\beta = 0.8$ the lower and the best upper bounds coincide up to three or four decimals and thus give almost exact results. Although the Monte Carlo price estimate is slightly higher, the interval $[\text{MC} - \text{SE}, \text{MC} + \text{SE}]$ overlaps with the interval $[\text{LB}A, \text{UB}A_d]$ for $A = \text{FA}$ or $A = \text{GA}$. Notice that for $\beta = 0.8$ ($\sigma = 0.2, 0.3$)—which is a case of theoretical interest as this rarely happens in practice—the values of PECUB GA and $\text{ICUB } B_T$ suffer from numerical instabilities caused by the involved numerical integration.
2. For $\sigma = 0.2$ and 0.3 , and $\beta = 1.1$ the value for upper bound UB FA_d is larger than the one for UB FA which must be caused by the additional Hölder inequality in the derivation of the error bound $\varepsilon(\tilde{d}_{\text{FA}})$.
3. The partially exact/comonotonic upper bound PECUB GA is the best of all upper bounds for $\sigma = 0.2$ and $\beta = 1.1$.

4. Conclusions and future research

We derived analytical lower and upper bounds for the price of European-style discrete arithmetic Asian options with fixed and floating strike. Hereto we used and combined different ideas and techniques such as firstly conditioning on some random variable as in [21], secondly results based on comonotonic risks and bounds for stop-loss premiums of sums of dependent random variables as in [15], and finally adaptation of the error bound of Rogers and Shi as in [19]. All bounds have analytical expressions. This allows a study of the hedging Greeks of these bounds. For the numerical experiments it was important to find and motivate a good choice for the conditioning variables appearing in the formulae. We note that the expressions found for the bounds are not only analytical but also easily computable. The numerical results in the tables show that the upper bounds UB GA_d or UB FA_d are in general the best ones except for extreme values of the strike price K or β ; then $\text{ICUB } B_T$ or PECUB GA outperforms all the other upper bounds. The lower bounds LB GA and LB FA are practically equal and very close to the Monte Carlo values.

This approach has also been used to derive upper and lower bounds for basket options and Asian basket options, see Deelstra et al. [8]. The derivation of bounds for Asian options by using binomial trees was investigated in [20].

We mention that in view of recent developments for modelling the asset prices by exponential Lévy processes, Albrecher and Predota [2,3] have applied the comonotonic upper bound of Kaas et al. [15] when the asset price dynamics is driven by a Normal Inverse Gaussian (NIG) and Variance Gamma (VG)

Lévy processes. Moreover, Albrecher et al. [1] present a general case of this upper bound and illustrate super-hedging of Asian options using European call options in a buy-and-hold strategy. We note also that in context of Lévy processes the results on the equivalence between fixed and floating strike Asian options are recently derived in [11].

Further research includes extending the conditioning approach to more general distributions than lognormal. For example, one candidate is the class of log-elliptic distributions which is a better choice from the point of view of providing a better fit to the real data (cf. [24]).

Appendix A. Some theoretical results

In this section, we recall from Dhaene et al. [9] and the references therein the procedures for obtaining the lower and upper bounds for stop-loss premiums of sums \mathbb{S} of dependent random variables by using the notion of comonotonicity and of convex ordering, see Section 2.1.

A.1. Improved comonotonic upper bound

As proven in [9], the convex-largest sum of the components of a random vector with given marginals is obtained by the comonotonic sum \mathbb{S}^c , see (2). In the following theorem Dhaene et al. [9] have proved that the stop-loss premiums of a sum of comonotonic random variables can easily be obtained from the stop-loss premiums of the terms.

Theorem 10. *The stop-loss premiums of the sum \mathbb{S}^c of the components of the comonotonic random vector $(X_1^c, X_2^c, \dots, X_n^c)$ are given by*

$$E[(\mathbb{S}^c - d)_+] = \sum_{i=1}^n E[(X_i - F_{X_i}^{-1}(F_{\mathbb{S}^c}(d)))_+], \quad (F_{\mathbb{S}^c}^{-1}(0) < d < F_{\mathbb{S}^c}^{-1}(1)).$$

Let us now assume that we have some additional information available concerning the stochastic nature of (X_1, \dots, X_n) . More precisely, we assume that there exists some random variable A with a given distribution function, such that we know the conditional cumulative distribution functions, given $A = \lambda$, of the random variables X_i , for all possible values of λ . In fact, Kaas et al. [15] define the improved comonotonic upper bound \mathbb{S}^u as in (3). Notice that

$$\mathbb{S}^u = \left(\sum_{i=1}^n X_i \mid A \right)^c.$$

In order to obtain the distribution function of \mathbb{S}^u , observe that given the event $A = \lambda$, the random variable \mathbb{S}^u is a sum of comonotonic random variables. Hence,

$$F_{\mathbb{S}^u|A=\lambda}^{-1}(p) = \sum_{i=1}^n F_{X_i|A=\lambda}^{-1}(p), \quad p \in [0, 1].$$

Given $A = \lambda$, the cdf of \mathbb{S}^u is defined by

$$F_{\mathbb{S}^u|A=\lambda}(x) = \sup \left\{ p \in [0, 1] \mid \sum_{i=1}^n F_{X_i|A=\lambda}^{-1}(p) \leq x \right\}.$$

The cdf of \mathbb{S}^u then follows from

$$F_{\mathbb{S}^u}(x) = \int_{-\infty}^{+\infty} F_{\mathbb{S}^u|A=\lambda}(x) dF_A(\lambda).$$

If the marginal cdfs $F_{X_i|A=\lambda}$ are strictly increasing and continuous, then $F_{\mathbb{S}^u|A=\lambda}(x)$ is a solution to

$$\sum_{i=1}^n F_{X_i|A=\lambda}^{-1}(F_{\mathbb{S}^u|A=\lambda}(x)) = x, \quad x \in (F_{\mathbb{S}^u|A=\lambda}^{-1}(0), F_{\mathbb{S}^u|A=\lambda}^{-1}(1)). \quad (60)$$

In this case, we also find that for any $d \in (F_{\mathbb{S}^u|A=\lambda}^{-1}(0), F_{\mathbb{S}^u|A=\lambda}^{-1}(1))$:

$$E[(\mathbb{S}^u - d)_+ \mid A = \lambda] = \sum_{i=1}^n E[(X_i - F_{X_i|A=\lambda}^{-1}(F_{\mathbb{S}^u|A=\lambda}(d)))_+ \mid A = \lambda] \quad (61)$$

from which the stop-loss premium at retention d of \mathbb{S}^u can be determined by integration with respect to λ .

A.2. Lower bound

Let $\underline{X} = (X_1, \dots, X_n)$ be a random vector with given marginal cdfs $F_{X_1}, F_{X_2}, \dots, F_{X_n}$. We assume as in the previous section that there exists some random variable A with a given distribution function, such that we know the conditional cdfs, given $A = \lambda$, of the random variables X_i , for all possible values of λ . This random variable A , however, should not be the same as in case of the upper bound. We recall from Kaas et al. [15] how to obtain a lower bound, in the sense of convex order, for $\mathbb{S} = X_1 + X_2 + \dots + X_n$ by conditioning on this random variable.

For the conditional expectation \mathbb{S}^ℓ , see (4), let us further assume that the random variable A is such that all $E[X_i \mid A]$ are nondecreasing and continuous functions of A . The quantiles of the lower bound \mathbb{S}^ℓ then follow from

$$F_{\mathbb{S}^\ell}^{-1}(p) = \sum_{i=1}^n F_{E[X_i|A]}^{-1}(p) = \sum_{i=1}^n E[X_i \mid A = F_A^{-1}(p)], \quad p \in [0, 1]$$

and the cdf of \mathbb{S}^ℓ is given by

$$F_{\mathbb{S}^\ell}(x) = \sup \left\{ p \in [0, 1] \mid \sum_{i=1}^n E[X_i \mid \mathcal{A} = F_{\mathcal{A}}^{-1}(p)] \leq x \right\}.$$

If we now additionally assume that the cdfs of the random variables $E[X_i \mid \mathcal{A}]$ are strictly increasing and continuous, then the cdf of \mathbb{S}^ℓ is also strictly increasing and continuous, and we get for all $x \in (F_{\mathbb{S}^\ell}^{-1}(0), F_{\mathbb{S}^\ell}^{-1}(1))$,

$$\sum_{i=1}^n F_{E[X_i \mid \mathcal{A}]}^{-1}(F_{\mathbb{S}^\ell}(x)) = x \Leftrightarrow \sum_{i=1}^n E[X_i \mid \mathcal{A} = F_{\mathcal{A}}^{-1}(F_{\mathbb{S}^\ell}(x))] = x, \quad (62)$$

which unambiguously determines the cdf of the convex order lower bound \mathbb{S}^ℓ for \mathbb{S} . Using Theorem 10, the stop-loss premiums of \mathbb{S}^ℓ can be computed as

$$E[(\mathbb{S}^\ell - d)_+] = \sum_{i=1}^n E[(E[X_i \mid \mathcal{A}] - E[X_i \mid \mathcal{A} = F_{\mathcal{A}}^{-1}(F_{\mathbb{S}^\ell}(d))])_+], \quad (63)$$

which holds for all retentions $d \in (F_{\mathbb{S}^\ell}^{-1}(0), F_{\mathbb{S}^\ell}^{-1}(1))$.

So far, we considered the case that all $E[X_i \mid \mathcal{A}]$ are nondecreasing functions of \mathcal{A} . The case where all $E[X_i \mid \mathcal{A}]$ are nonincreasing and continuous functions of \mathcal{A} also leads to a comonotonic vector $(E[X_1 \mid \mathcal{A}], E[X_2 \mid \mathcal{A}], \dots, E[X_n \mid \mathcal{A}])$, and can be treated in a similar way.

A.3. Sums of lognormal variables

In this section, we study upper and lower bounds for $E[(\mathbb{S} - d)_+]$ where \mathbb{S} is a linear combination of lognormal variables. Let us denote

$$\mathbb{S} = \sum_{i=1}^n X_i = \sum_{i=1}^n \alpha_i e^{Y_i}, \quad (64)$$

with Y_i a normally distributed random variable with mean $E[Y_i]$ and variance $\sigma_{Y_i}^2$, and $\alpha_i \in \mathbb{R}$.

In this case the stop-loss premium with some retention d_i , namely $E[(X_i - d_i)_+]$, can be obtained from the following theorem:

Theorem 11. Let X_i be a lognormal random variable of the form $X_i = \alpha_i e^{Y_i}$ with

$$Y_i \sim N(E[Y_i], \sigma_{Y_i})$$

and $\alpha_i \in \mathbb{R}$. Then the stop-loss premium with retention d_i equals for $\alpha_i d_i > 0$

$$E[(X_i - d_i)_+] = \text{sign}(\alpha_i) e^{\mu_i + \frac{\sigma_i^2}{2}} \Phi(\text{sign}(\alpha_i) d_{i,1}) - d_i \Phi(\text{sign}(\alpha_i) d_{i,2}), \quad (65)$$

where Φ is the cdf of the $N(0, 1)$ distribution, and $d_{i,1}$ and $d_{i,2}$ are determined by

$$d_{i,1} = \frac{\mu_i + \sigma_i^2 - \ln |d_i|}{\sigma_i}, \quad d_{i,2} = d_{i,1} - \sigma_i. \quad (66)$$

The cases $\alpha_i d_i < 0$ are trivial.

We now consider a normally distributed random variable A and we slightly generalize Theorem 1 of Dhaene et al. [10] to our more general settings.

Theorem 12. *Let \mathbb{S} be given by (64) and consider a normally distributed random variable A such that (Y_i, A) is bivariate normally distributed for all i . Then the distributions of the improved comonotonic upper bound \mathbb{S}^u and the lower bound \mathbb{S}^ℓ are given by*

$$\mathbb{S}^u \stackrel{d}{=} \sum_{i=1}^n F_{X_i|A}^{-1}(U) = \sum_{i=1}^n \alpha_i e^{E[Y_i] + r_i \sigma_{Y_i} \Phi^{-1}(V) + \text{sign}(\alpha_i) \sqrt{1-r_i^2} \sigma_{Y_i} \Phi^{-1}(U)}, \quad (67)$$

$$\mathbb{S}^\ell \stackrel{d}{=} \sum_{i=1}^n E[X_i | A] = \sum_{i=1}^n \alpha_i e^{E[Y_i] + r_i \sigma_{Y_i} \Phi^{-1}(V) + \frac{1}{2} (1-r_i^2) \sigma_{Y_i}^2}, \quad (68)$$

where U and $V = \Phi((A - E[A])/\sigma_A)$ are mutually independent uniform $(0, 1)$ random variables, Φ is the cdf of the $N(0, 1)$ distribution and r_i is defined by

$$r_i = \text{corr}(Y_i, A) = \frac{\text{cov}[Y_i, A]}{\sigma_{Y_i} \sigma_A}.$$

When for all i $\text{sign}(\alpha_i) = \text{sign}(r_i)$ for $r_i \neq 0$, or for all i $\text{sign}(\alpha_i) = -\text{sign}(r_i)$ for $r_i \neq 0$, then \mathbb{S}^ℓ is comonotonic.

Appendix B. Proof of symmetry results in Theorem 9

Proof of Theorem 9 (Symmetry results). We only prove the first symmetry result since the others follow along similar lines.

$$\begin{aligned} & \text{AP}(K, S(0), r, \delta, T, n, T - n + 1) \\ &= e^{-rT} E^Q \left[\left(K - \frac{1}{n} \sum_{i=0}^{n-1} S(T - i) \right)_+ \right] \\ &= e^{-\delta T} E^Q \left[\frac{e^{-(r-\delta)T} S(T)}{S(0)} \left(\frac{KS(0)}{S(T)} - \frac{1}{n} \sum_{i=0}^{n-1} \frac{S(T - i)S(0)}{S(T)} \right)_+ \right] \\ &= e^{-\delta T} E^{\tilde{Q}} \left[\left(\frac{KS(0)}{S(T)} - \frac{1}{n} \sum_{i=0}^{n-1} S(0) \exp \left[- \left(r - \delta + \frac{\sigma^2}{2} \right) i + \sigma(\tilde{B}(T - i) - \tilde{B}(T)) \right] \right)_+ \right], \end{aligned}$$

where we defined as before the probability \tilde{Q} equivalent to Q by the Radon–Nikodym derivative but now by stressing the dividend yield δ

$$\frac{d\tilde{Q}}{dQ} = \frac{S(T)}{S(0)e^{(r-\delta)T}} = \exp\left(-\frac{\sigma^2}{2}T + \sigma B(T)\right).$$

Under this probability \tilde{Q} , $\tilde{B}(t) = B(t) - \sigma t$ is a Brownian motion and therefore, the dynamics of the share under \tilde{Q} are given by

$$\frac{dS(t)}{S(t)} = ((r - \delta) + \sigma^2) dt + \sigma d\tilde{B}(t).$$

Due to the independent increments, $\tilde{B}(T - i) - \tilde{B}(T)$ has the same distribution as $\tilde{B}(i)$ and $-\tilde{B}(i)$, and we can concentrate on the process $(S^*(t))_t$ defined by

$$S^*(i) = S(0) \exp\left[-\left(r - \delta + \frac{\sigma^2}{2}\right)i + \sigma \tilde{B}(i)\right].$$

Indeed, then

$$\begin{aligned} \text{AP}(K, S(0), r, \delta, T, n, T - n + 1) &= e^{-\delta T} E^{\tilde{Q}} \left[\left(\frac{KS^*(T)}{S(0)} - \frac{1}{n} \sum_{i=0}^{n-1} S^*(i) \right)_+ \right] \\ &= e^{-\delta T} E^Q \left[\left(\frac{K\tilde{S}(T)}{S(0)} - \frac{1}{n} \sum_{i=0}^{n-1} \tilde{S}(i) \right)_+ \right] \end{aligned}$$

with the process $(\tilde{S}(t))_t$ defined by

$$\tilde{S}(i) = S(0) \exp\left[-\left(r - \delta + \frac{\sigma^2}{2}\right)i + \sigma B(i)\right]$$

with $(B(t))_t$ a Brownian motion under Q .

As a conclusion,

$$\text{AP}(K, S(0), r, \delta, T, n, T - n + 1) = \text{ACF}\left(S(0), \frac{K}{S(0)}, \delta, r, T, n, 0\right),$$

which was to be shown. \square
